Chapter 1

Introduction

1.1 Hyaluronan (HA)

Hyaluronan (HA) was first described in 1934 by Mayer and Palmer as a polysaccharide found in vitreous body of bovine eye [Meyer and Palmer 1934]. Hyaluronan belongs to the family of glucosaminoglycans (GAGs). The GAG family is defined by linear carbohydrate polymers consisting of disaccharide units. In proteoglycans, protein cores are posttranslationally modified by glycosyltransferases in the Golgi apparatus, where GAGs are added to protein cores. In contrast to the other GAGs, hyaluronan is not sulfated, lacks the protein core and is synthesized on the plasma membrane [Fraser et al. 1997]. Hyaluronan is synthesized by addition of alternating N-acetylglucosamine and D-glucuronic acid linked by $\beta(1-4)$ and $\beta(1-3)$ bonds (Figure 1.1). In average, hyaluronan consists of approximately 25,000 disaccharide units, which is corresponding to 10 μm extended length [Fessler and Fessler 1966]. Hyaluronan can range in size from 5 to 20,000 kDa *in vivo*.

Figure 1.1: **Structure of Hyaluronan**

1.2 HA Metabolism

HA is synthesized by enzymes named hyaluronan synthases and degraded by hyaluronidases. The turnover of HA in the human body occurs rapidly. Around one third of hyaluronan in the human body is turned over each day.

1.2.1 Hyaluronan synthases (HAS)

The mammalian hyaluronan synthases were cloned in 1996 and 1997. The first cloned HAS was the murine HAS1, which was highly expressed in brain and to a lesser extent in liver, skeletal muscle and pancreas [Itano and Kimata 1996a]. Later the same year, human HAS1 was isolated through screening of a human cDNA library in an attempt to find cDNA clones that encode proteins, which could bind to a T-cell lymphoma cell line [Shyjan et al. 1996]. Human HAS1 is the homologue of mouse HAS1 that shared 96% amino acid homology, and developed from the same original gene. Northern blot experiments showed that the human HAS1 mRNA is highly expressed in ovary [Shyjan et al. 1996].

In the same year, human and murine HAS2 were isolated by Spicer and colleagues. The murine HAS2 is highly expressed in the mouse embryo and in adult tissues such as brain, spleen and lung. Northern blot analysis showed two bands at 3.2 kb and 4.8 kb [Spicer et al. 1996]. This indicates that there are two transcriptional splicing variants for HAS2. However, no annotation for the shorter splicing variant of HAS2 was entered to the Genbank database.

In 1997, Spicer and colleagues reported that the third HAS gene was detected in both human and mouse named HAS3 [Spicer et al. 1997a]. They also showed that there were two transcriptional splicing variants (6.5kb and 4kb) of

mouse HAS3 by northern blot. In 2002, it was revealed that human HAS3 also has two splicing variants [Sayo et al. 2002; Monslow et al. 2003]. Northern blot analysis showed two bands of 4.8 kb and 2 kb.

In human and mouse, the three HAS genes are localized on different chromosomes [Spicer et al. 1997b] and evidence indicates that gene duplication induced the three HAS isoforms by evolution. After the first gene duplication, HAS1 and HAS2 genes were formed. Then, the HAS1 gene was duplicated to generate HAS1 pseudogene (found in *Xenopus laevis*, xHas-rs) and the HAS3 gene is formed by HAS2 duplication, respectively [Spicer and McDonald 1998]. The HAS1 pseudogene could not yet be detected in mammals [DeAngelis 1999]. Disruption of HAS2 causes embryonic lethality at E9.5 in mice, whereas deletion of HAS1 and HAS3 showed no obvious phenotype during embryonic development [Camenisch et al. 2002].

Topology of HAS isoforms

As in Figure 1.2, the HAS enzymes are localized in the plasma membrane and the topological prediction shows that they span the membrane seven times with the active site presumably located in the large cytoplasmic loop [Weigel et al. 1997]. Studies on raw membrane preparations showed that the sugars were added to the reducing end of the chain [Weigel et al. 1997; Asplund et al. 1998; Itano and Kimata 1996b]. The enzymatic activity of hyaluronan synthases is referred to the glycosyltransferase of both glucuronic acid and acetylglucosamine. Site directed mutagenesis experiments showed that the active center of HAS likely resides in the large intracellular loop between the second and the third transmembrane domain [Yoshida et al. 2000]. Polymerization of HA is thought to occur at the cytoplasmic active center of HAS and the growing polymer is

Figure 1.2: **Predicted topological structure of eukaryotic and bacterial hyaluronan synthases.**

Very similar hydropathy plots and primary structure (28 - 71 % identity) among all the HAS isozymes suggest that they are similarly organized within the membrane. The scheme depicts the N- and C-termini and the large central domain, between MD2 and MD3, inside the cell. The larger eukaryotic HASs (red line) have additional amino acids in all regions compared to the bacterial HASs (green line), except for the highly conserved 178 amino acids carboxyl terminal of the central domain and MD1-MD5. In particular, the carboxyl terminal ~25 % of the eukaryotic HASs has two additional predicted membrane domains (MD6 and MD7), missing in the bacterial proteins. The conserved Cys is indicated by the *circled C*. MD5 can be modeled as an amphipathic helix, which orients the C terminus of all HAS members inside. (Modified from [Weigel et al. 1997])

extruded to the outside of the cell during elongation. HA is exported to the extracellular matrix either by the HAS enzyme itself or through one of the ABC transporters or the combination of both [DeAngelis and Weigel 1994; DeAngelis and Achyuthan 1996; Schulz et al. 2007; Prehm and Schumacher 2004].

Activity of HAS isoforms

All three HAS isoforms catalyze the same reaction. Even though, each HAS isoform produces HA of different length with different enzymatic kinetics [Itano et al. 1999a]. HAS1 and HAS2 produce high molecular weight (HMW) HA with the average size of 2×10^6 Da, whereas the product of HAS3 is about 2×10^5 Da in size [Spicer et al. 1997a; Itano et al. 1999a; Brinck and Heldin 1999]. *In vitro* study indicated that HAS enzyme could polymerize 10 - 100 UDP sugar precursors per second [DeAngelis 1999]. Thus, it takes a HAS enzyme 5 - 10 minutes to produce HA chain with 1 - 10×10^6 Da in length *in vitro*.

Splicing variants of HAS3

Two splicing variants of human HAS3 were discovered, namely HAS3v1 and HAS3v2. Figure 1.3 A shows the genomic structure of human HAS3 gene annotated in the Genbank. HAS3v2 spreads longer on the genome than HAS3v1. Thus, HAS3v1 consists of 553 AA while HAS3v2 is only 281 AA in length. This is due to the fact that the coding sequence on the last exon of HAS3v2 is shorter. The difference in the 5' UTR (untranslated region) between HAS3v1 and HAS3v2 indicates the diverse transcriptional regulation. HAS3v1 and HAS3v2 share the first two coding exons, which causes that the first 246 amino acid from HAS3v1 and HAS3v2 are identical. Homology analysis reveals that HAS3v2 is

Figure 1.3: **HAS3v1 and HAS3v2 are close related**

(**A**): Genomic structure of HAS3 splicing variants; (**B**): Homology analysis of HAS isoforms.

closer related to HAS3v1 than HAS2 and HAS1 (figure 1.3 B). No report has yet addressed human HAS3v2 except the first detection [Sayo et al. 2002; Monslow et al. 2003].

1.2.2 Hyaluronidases (HYAL)

Enzymes that are capable to degrade hyaluronan are known as hyaluronidases.

There are six genes in mammals that encode hyaluronidases. These six hyaluronidase

Chromosomal cluster	Gene	Protein	Degradation product of HA	physiological expression pattern	Optimal PH
3p21.3	Hyal1	Hyal1	tetra- & hexa-saccharides	serum, liver, kidney, heart	3-4

	SPAM1	PH20	tetra- & hexa-saccharides	Testis	4.5, 7.5
	HyalP1	None	-	-	-

Table 1.1: **The six hyaluronidase paralogues in human genome**

n.d.-not determined

genes are localized to two gene clusters on the chromosomes 3p21 and 7q31 in human.

Hyaluronidase 1 (HYAL1) is originally isolated from serum [Frost et al. 1997]. The molecular weight of human Hyal1 is 45 kDa after translation, and 8 kDa is added by the post-translational glycosylation. The enzymatic activity of HYAL1 is optimal at an acidic pH. HYAL2 is approximately 40 % paralogous to HYAL1. HYAL2 can only cleave hyaluronan into an intermediate size (about 20 kDa). In mice, HYAL2 is expressed in the brain during the fetal development and silenced after birth [Strobl et al. 1998; Lepperdinger et al. 2001]. This indicates the HYAL2 plays an important role in embryonic development of brain. HYAL2 can attach to the surface of cell membrane as a GPI anchored protein, which may work as a receptor for an oncogenic virus, namely Jaagsiekte sheep retrovirus [Rai et al. 2001]. PH20 is expressed in the testis in two forms. During the fertilization, one form of PH20 is localized on the surface of the acrosomal head of the sperm to enable the sperm to penetrate the HA-rich ECM of the cumulus cells surrounding the egg. Then, the other form of PH20, which is localized in the acrosomal vesicle, is required for the sperm to degrade the surface associated HA and to bind to the surface of the egg cell [Kreil 1995]. Table 1.1 shows the known enzymatic properties of human hyaluronidases.

The mammalian hyaluronidases function as β -endo-N-acetyl-glucosaminidases, which degrade not only hyaluronan but also other GAGs such as chondroitin sulfate and dermatan sulfate [Batra et al. 1997]. To date, the HA specific hyaluronidases are only discovered in *Streptococci Pneumococcus* and *Streptomyces hyalurolyticus*.

Figure 1.4: **Pericellular hyaluronan coat**

Chondrocytes were fixed and incubated with uranyl acetate in suspension, then examined using ESEM (environmental scanning electron microscopy). **(A)** Untreated cells are surrounded by a 4.4 ± 0.7 -mm-thick hyaluronan coat (arrow). **(B)** Hyaluronidase removed the pericellular hyaluronan coat completely. Scale bar, 5 mm. [Zaidel-Bar et al. 2004]

1.3 Localizatioin of HA

1.3.1 Extracellular hyaluronan

Hyaluronan is a key component of the extracellular matrix (ECM). During synthesis, the growing polymer chain is extruded through the membrane into the pericellular space. After synthesis, hyaluronan can be retained on the cell surface to form a voluminous pericellular matrix (pericellular coat). Figure 1.4 shows the hyaluronan dependent pericellular matrix in Chondrocytes [Zaidel-Bar et al. 2004]. This pericellular hyaluronan matrix plays multiple roles in cell adhesion/detachment, and cell shape changes associated with proliferation and locomotion. By overexpressing the hyaluronan synthases, microvillous membrane protrusions were observed that form the scaffold of hyaluronan coats in certain cells [Rilla et al. 2005; Kultti et al. 2006]. Hyaluronan is crosslinked by

various proteins, such as aggrecan, TSG-6, inter-alpha-trypsin inhibitor, versican and brevican [Day and Prestwich 2002]. This enables hyaluronan to gain different functions such as inflammatory response.

1.3.2 Intracellular hyaluronan

In 1976, it was first reported by Margolis and colleagues that glycosaminoglycans are enriched in the rat brain nuclei and hyaluronan accounts for nearly 1/3 of the total quantity [Margolis et al. 1976]. Intense HA staining was observed in rough endoplasmic reticulum (rER) membranes (but not lumen), plasma membranes, and nuclei in all the tissues studied [Londoño and Bendayan 1988; Kan 1990; Ripellino et al. 1988; Eggli and Graber 1995]. Intracellular HA can be accumulated under hyperglycemia condition [Wang and Hascall 2009]. Evanko and Wight showed that HA accumulated intracellularly in the perinuclear region of aortic smooth muscle cells during the premitotic and mitotic stages [Evanko and Wight 1999]. However, the source of the intracellular HA is not yet clear. A recent study treated viable smooth muscle cells with hyaluronidase to remove pericellular HA to prevent the internalization. This eliminated most but not all of the intracellular HA. This supports the conclusion that a large proportion might be due to endocytosis uptake. Further, exogenous fluorescein-labeled hyaluronan was taken up into vesicles in growing cells but was localized distinctly compared to endogenous hyaluronan, suggesting that hyaluronan in cells may be derived from an intracellular source [Evanko and Wight 1999].

1.3.3 Intracellular hyaladherins

The identification of intracellular HA-binding proteins (IHABPs), including RHAMM, IHABP4, CDC37 and HABP1, lends additional support to the existence of intracellular HA [Day and Prestwich 2002; Assmann et al. 1998; Hofmann et al. 1998; Huang et al. 2000; Turley et al. 2002]. RHAMM is one of the well-studied HA receptors. The precise function of RHAMM is described in a subsequent section (see section 1.4.2). Human IHABP4 is 57 kDa in size. IHABP4 is a cytoplasmic and nuclear protein that can be phosphorylated on serine and threonine residues. IHABP4 could bind to hyaluronan as well as chondroitin sulfate, heparane sulfate, and RNA though with low affinity. The IHABP4 expression is enriched in some tumor cells [Kobarg et al. 1997]. IHABP4 was shown to associate with RACK1/PKC pathway for regulating the cellular functions [Nery et al. 2004]. In 1995, Grammatikakis and colleagues showed that cell cycle control protein, CDC37, could bind to hyaluronan, chondroitin sulfate and heparin *in vitro* [Grammatikakis et al. 1995]. It still unknown whether cell division could be modified by cdc37 after binding to HA. HABP1 was first isolated from rat kidney by HA sepharose affinity chromatography [Gupta et al. 1991]. The GAG binding affinity of HABP1 is restricted to hyaluronan. HABP1 coated culture plates allowed more cell to attach [Gupta and Datta 1991]. Subcellularly, HABP1 localized in the mitochondrial matrix, cytoplasm, nuclear and also on the plasma membrane [Gupta et al. 1991; Muta et al. 1997; Dedio et al. 1998; Simos and Georgatos 1994]. Activated ERK, one of the MAP kinases, can phosphorylate HABP1 [Majumdar et al. 2002]. Phorbol 12-myristate 13-acetate (PMA) can decrease HABP1 in cytoplasm with parallel increase in the nucleus by activating ERK. This indicates that HABP1 contributes in part to the MAP kinase cascade implying a broad role in signaling. Furthermore, HABP1 was up-regulated at

both mRNA and protein level during cisplatin and TNF-alpha-induced apoptosis [Kamal and Datta 2006; Guo et al. 1999]. Ectopic expression of HABP1 induces apoptosis, autophagic vacuoles and mitochondrial dysfunction [Meenakshi et al. 2003; Sengupta et al. 2004; Chowdhury et al. 2008]. Overexpression of HABP1 was observed in a variety of adenocarcinomas including thyroid, colon, gastric, esophageal and lung adenocarcinoma [Rubinstein et al. 2004].

1.4 Physiological function of HA

1.4.1 Physical function of HA

HA has diverse functions despite of its unbranched simple composition. The axial hydrogen atoms create a non-polar, relatively hydrophobic core while the equatorial side chains produce a more polar, hydrophilic surface, thereby inducing a twisting ribbon structure. As a result, the hyaluronan molecule can randomly fold to coiled structure under physiological conditions and occupy a very large space [Scott et al. 1991]. HA binds a huge amount of water in the extracellular space and thus hydrates tissues and skin dermis. Hyaluronan regulates water balance, osmotic pressure and acts as an ion exchange resin. Furthermore, HA forms a thin layer in the luminal surface of blood vessel, named apical glycocalyx that excludes certain macromolecules, leukocytes and platelets from direct interaction with the luminal surface of endothelial cells [Henry and Duling 1999]. As a lubricant and a shock absorber, hyaluronan acts as a structural molecule in the vitreous humor of the eye, in joint fluid, and in Wharton's jelly [Toole 2004].

1.4.2 HA receptors and intracellular signaling pathways.

It is now known that HA plays an important role in modulating cell behavior. Hyaluronan regulates cell motility, cell-cell and cell-matrix adhesion, cell proliferation and differentiation. It participates in fundamental processes such as embryological development and morphogenesis [Toole 1990, 2001], wound healing [Weigel et al. 1988; Longaker et al. 1991], repair and regeneration and inflammation [Noble 2002; De la Motte et al. 2003; Majors et al. 2003]. HA regulates the intracellular signaling pathways by binding to the proteins known as hyal-adherins including LYVE1 (Lymphatic Vessel Endothelial Receptor 1), HARE (Hyaluronan Receptor for Endocytosis), toll-like receptors TLR and TLR4, CD44 (Cluster of Differentiation 44) and RHAMM (Receptor for Hyaluronan Mediated Motility).

RHAMM

RHAMM localizes both intracellularly and on the outer plasma membrane, although, there is no signal peptide or transmembrane domains encoded [Turley 1980]. Intracellularly, RHAMM exists in the cytoplasm, mitochondria and nucleus [Assmann et al. 1999; Crainie et al. 1999; Entwistle et al. 1996; Lynn et al. 2001]. RHAMM interacts with cytoskeleton, microtubules, centrosomes and mitotic spindle [Assmann et al. 1999; Maxwell et al. 2003]. RHAMM is engaged in different cellular functions including cell transformation and proliferation. Overexpression of RHAMM leads to ras-dependent cell transformation in fibroblasts [Hall et al. 1995]. It also influences cell mitosis by inducing the expression of cdc25 and cyclin B1, which are both involved in cell cycle regulation [Mohapatra et al. 1996]. The expression of RHAMM is also differentially regulated during

the different phases of the cell cycle [Sohr and Engeland 2008]. The mRNA and protein levels of RHAMM are elevated during the S-phase and peak during the mitotic phase (G2/M). HA accumulates during the mitosis for cell detachment [Brecht et al. 1986]. Further, RHAMM expression can be down-regulated by the tumor suppressor P53. Therefore, HA-RHAMM interaction might play an important role in cell cycle regulation and thereby RHAMM is significantly involved in cancer progression. A current model of HA-dependent RHAMM mediated signaling pathways is demonstrated in figure 1.5 [Turley et al. 2002].

The basal expression level of RHAMM is low in normal tissues [Turley et al. 2002; Evanko et al. 2007; Slevin et al. 2007]. Deficiency of RHAMM in mice showed no obvious effect on embryonic development and adult mouse homeostasis but revealed delayed wound healing [Crainie et al. 1999; Nedvetzki et al. 2004; Tolg et al. 2006]. However, up-regulation of RHAMM was reported in several advanced cancers [Giannopoulos and Schmitt 2006; Hus et al. 2008; Rein et al. 2003; Tolg et al. 2003; Yamano et al. 2008; Zlobec et al. 2008]. For example, RHAMM is defined as a breast cancer susceptibility gene [Pujana et al. 2007]. The interaction between HA and RHAMM activates multiple signaling pathways that affect the motility and progression of breast cancer cells [Turley et al. 2002]. Higher expression of RHAMM in breast cancer is associated with poorer clinical prognosis and higher risk of lymph node metastasis [Assmann et al. 2001; Wang et al. 1998].

CD44

CD44 belongs to the class 1 transmembrane glycoprotein family and functions as a ubiquitous cell surface receptor of hyaluronan. CD44 is a single copy gene and highly conserved [Screaton et al. 1992]. CD44 transcripts are subject to

Figure 1.5: **HA-dependent RHAMM mediated signaling pathways**

RHAMM is a hyaladherin that occurs in multiple subcellular compartments and that can also be exported to the extracellular milieu where it binds to the cell surface. Cell surface RHAMM-hyaluronan interactions regulate signaling through Ras and Src. Cell surface RHAMM stimulates the PDGF receptor to activate Erk kinase, a key map kinase involved in cell motility. Intracellular RHAMM proteins encode multiple kinase docking and recognition sites, and an intracellular form of RHAMM has been shown to physically associate with Erk1 kinase. Intracellular forms also associate with the cytoskeleton, notably interphase and mitotic spindle microtubules. The ability of intracellular RHAMM to associate with multiple signaling complexes and to associate with the cytoskeleton suggest that RHAMM functions as adapter proteins like vinculin and paxillin. FAK, focal adhesion kinase. (Modified from [Turley et al. 2002])

alternative splicing, which affects predominantly the extracellular membrane-proximal part of CD44 proteins [Stamenkovic et al. 1991; Günthert et al. 1991]. The standard isoform of CD44 consists of an N-terminal signal sequence (exon 1), a HA binding domain with homology to the link protein family of aggrecan and HA binding proteins (exons 2 and 3), a stem region of 248 amino acids (Exons 4, 5, 16, 17), a 21 amino acid transmembrane domain (exon 18), and a 72 amino acid cytoplasmic domain (exon 19). The splice variants are generated as a result of insertion of various permutations and combinations of exons 6-15 (v1-v10) into the stem region. CD44 isoforms are broadly expressed and range from 80 to 200 kDa in size. The mRNA and protein structures of CD44 splicing variants are shown in figure 1.6. The variants are most commonly expressed in epithelial cells and are upregulated under pathological conditions such as cancer [Screaton et al. 1992; Stamenkovic et al. 1991; Goldstein and Butcher 1990].

CD44 can be regulated at multiple levels: promoter methylation, transcription, post-translational modifications such as glycosylation, glycosaminoglycan interaction, and phosphorylation, ligand binding, and proteolytic processing of the extracellular domain [Lou et al. 1999; Verkaik et al. 1999; Yan et al. 2003; Borland et al. 1998; Greenfield et al. 1999; Zhang et al. 1995; Legg et al. 2002; Neame and Isacke 1992; Cichy and Puré 2003]. The binding of CD44 isoforms to hyaluronan contributes to the stimulation of aggregation, proliferation, migration, and angiogenesis [Lesley et al. 1993; Bourguignon et al. 1992, 1998; Lokeshwar et al. 1996]. The intracellular domain of CD44 isoforms selectively interacts with cytoskeletal proteins and regulates specific signalings such as PI 3 kinase pathway [Bourguignon et al. 1998]. Therefore, CD44 isoforms directly link with hyaluronan and the cytoskeleton. Figure 1.6 summarizes the signal cascades, which are regulated by hyaluronan-CD44 interaction.

Figure 1.6: **HA-dependent CD44 mediated signaling pathways**

CD44-hyaluronan interactions promote tyrosine kinase (TK) activity of HER2 and the non-receptor kinase, Src. Src phosphorylates cortactin, which recruits it to the cell membrane. CD44-hyaluronan interactions also activate RHOA and Rac1, and CD44 binds to Tiam1 and Vav2. Hyaluronan binding also causes the association of CD44 forms with cytoskeletal proteins such as ankyrin and ERM proteins. The current model suggests that the close interactions between CD44 and its selected binding partners play a pivotal role in coordinating cross-talk among various intracellular signaling pathways (e.g. Rho/Ras signaling and receptor-linked (p185HER2)/non-receptor-linked (c-Src) tyrosine kinase pathways) leading to the concomitant onset of multiple functions such as tumor cell adhesion, proliferation/growth, migration, and invasion. MLC, myosin light chains. (Modified from [Turley et al. 2002])

1.5 Hyaluronan in cancer

Hyaluronan is shown to be elevated in both the cancer epithelium and peritumoral stroma during cancer progression depending on the cancer type. Either is associated with an unfavorable outcome of the disease. Recently, it is shown that hyaluronan is not only a prognostic indicator but also a novel target of therapy [Nakazawa et al. 2006; Pályi-Krekke et al. 2007].

Tumor hyaluronan is correlated with the mRNA expression level of HAS isoforms [Pienimäki et al. 2001; Karvinen et al. 2003; Pasonen-Seppänen et al. 2003]. This indicates that transcriptional regulation may play an important role in determining the hyaluronan accumulation. HAS isoform expression is stimulated by growth factors like EGF, KGF and PDGF [Pienimäki et al. 2001; Karvinen et al. 2003; Pasonen-Seppänen et al. 2003; Jacobson et al. 2000]. Furthermore, the expression levels of both growth factors and their receptors are frequently induced in cancers. Growth factors from cancer and stromal cells may act in concert to stimulate hyaluronan synthesis [Jacobson et al. 2000]. Specifically, cancer cells may induce the stromal cells to produce a HA-enriched tissue structure, which is more appropriate for tumor growth [Knudson and Toole 1988; Edwards et al. 2005]. On the other hand, growth factors from stromal cells could stimulate cancer cell migration [Karnoub et al. 2007].

The malignant transformation of cells is frequently associated with aberrant HA synthesis and ECM gene expression [Weigel et al. 1997; Itano and Kimata 2002; Stern et al. 2006]. Both HAS1 and HAS2 expression are elevated in highly malignant cells transformed with v-src. This implies that HAS isoforms may be involved in different stages of malignant transformation although the HAS enzymes are not transformed by themselves [Toole 2004]. Furthermore,

overexpression of HAS2 and HAS3 genes resulted in HA over-production and increased tumorigenicity of fibrosarcoma, melanoma, and mesothelioma cells [Kosaki et al. 1999; Liu et al. 2001; Itano et al. 1999b]. The importance of HAS enzymes for tumor cell phenotypes is also supported by the finding that suppression of HAS2 or HAS3 diminished the tumorigenic potential in a variety of tumors [Koyama et al. 2007; Zoltan-Jones et al. 2003; Desmoulière et al. 2004; Löhr et al. 2001]. Elevated HAS1 expression and intronic gene splicing correlate with poor prognosis in human colon cancer, ovarian cancer, and multiple myelomas [Itano et al. 2004; Theocharis et al. 2003; Itano et al. 2002]. Although the above evidences strongly supports the pro-tumorigenic role of HAS, the tumor promoting ability of HAS up-regulation can not be generalized because HAS2 overexpression can e.g. also inhibit the tumorigenesis of glioma cells [Cheng et al. 2007].

1.5.1 Tumor cell derived hyaluronan

Hyaluronan positive cancer cells were detected in about half of the breast and prostate tumor cases and over 80 % of ovarian, colorectal and gastric cancers showed hyaluronan positive cancer cells [Auvinen et al. 2000; Ropponen et al. 1998; Lipponen et al. 2001; Anttila et al. 2000; Setälä et al. 1999]. In most cases, hyaluronan is detected around the plasma membrane, and it also occasionally exists in the cytoplasm and even in the nucleus [Auvinen et al. 2000; Ropponen et al. 1998]. The proportion of hyaluronan-positive cancer cells, as well as the intensity of hyaluronan staining on those cells, directly correlates with tumor grade and degrees of cell differentiation [Auvinen et al. 2000; Ropponen et al. 1998; Anttila et al. 2000; Setälä et al. 1999; Hautmann et al. 2001; Pirinen et al. 2001; Suwiwat et al. 2004]. Furthermore, cancer metastasis often derives

from primary tumors with high hyaluronan expression suggesting an active role in cancer metastasis [Anttila et al. 2000; Böhm et al. 2002]. Furthermore, high hyaluronan levels in the cancer cells associate with unfavorable outcomes, i.e. shortened overall survival (OS) time and disease free survival (DFS) time in breast, gastric and colorectal cancers [Auvinen et al. 2000; Ropponen et al. 1998; Setälä et al. 1999; Köbel et al. 2004]. However, other studies showed that accumulation of hyaluronan in tumor could serve as a favorable prognostic factor. In lung squamous cell carcinoma, de-differentiated cancer cells showed less HA staining compared to higher differentiated ones with a more promising prognosis [Pirinen et al. 1998]. Therefore, the role of hyaluronan and its association with progression and metastasis can not be generalized and needs to be studied in different cancer entities.

1.5.2 Hyaluronan in stromal tissue

Stromal hyaluronan is increased in breast tumors, and this increase was more prominent at the invasion front than in the central tumor areas [Bertrand et al. 1992; Ponting et al. 1993]. It was later confirmed that the increased stromal hyaluronan is not restricted to breast cancer but also present in prostate, ovarian, bladder, endometrial, thyroid carcinomas and lung adenocarcinomas [Auvinen et al. 2000; Lipponen et al. 2001; Anttila et al. 2000; Pirinen et al. 2001; Lokeshwar et al. 2001; Afify et al. 2005; Aaltomaa et al. 2002; Ekici et al. 2004; Posey et al. 2003; Hiltunen et al. 2002]. Stromal HA can be markedly induced in tissue with low basal HA level. For instance, the stromal HA increased up to 49 fold in grade 3 ovarian cancer [Hiltunen et al. 2002]. High grade and poorly differentiated tumors are often paralleled with intense stromal hyaluronan. Furthermore, high levels of HA in stroma are also associated with cancer

cell penetration of capsules, lymph vessels and nerves in prostate carcinomas, local lymph node infiltration in breast cancers and with distant metastasis in thyroid, ovarian and prostate cancers [Auvinen et al. 2000; Lipponen et al. 2001; Anttila et al. 2000; Böhm et al. 2002; Lokeshwar et al. 2001; Aaltomaa et al. 2002; Wernicke et al. 2003]. 50 % of the breast cancer patients with high stromal hyaluronan passed away during 5 years of follow up, while all patients with low stromal hyaluronan survived [Auvinen et al. 2000]. The corresponding survival rates in ovarian cancer were 25 % and 45 % [Anttila et al. 2000]. Concisely, tumors with intensive stromal hyaluronan are induced in proliferation and metastasis.

1.6 Esophageal cancer

Esophageal cancer is the 3rd most common gastrointestinal malignancy [Blot and McLaughlin 1999] and is the 6th most frequent cancer worldwide [Parkin et al. 1999]. The incidence rate of esophageal cancer dramatically varies in different geographical regions of the world [Gore 1997]. The highest incidence of the disease occurs in the Esophageal Cancer Belt which stretches from eastern Turkey to Iraq, Iran, China, India, and certain regions of South Africa [Ribeiro et al. 1996]. More than 90 % of the esophageal cancers are either squamous cell carcinomas (ESCC) or esophageal adenocarcinomas (EAC) [Blot 1995]. Although patient presentation of ESCC and EAC are similar, the epidemiology, etiology, prognosis and treatment strategy are quite different [Mariette et al. 2005; Siewert and Ott 2007]. ESCC and EAC are considered to represent two different diseases occurring in the same organ.

1.6.1 Epidemiology

Until the 1970s, ESCC was the dominant type of esophageal cancer. High incident regions of ESCC are in the Southern and Eastern Africa and a central Asian belt passing from Turkey through Iran, Iraq, Kazakhstan, Mongolei and onto Northern China. The incidence in high-risk areas can reach up to 100/10,000 per year compared to 5 -10/10,000 per year in Western countries [Holmes and Vaughan 2007]. Worldwide, the male:female ratio is 3:1. However, the distribution is more equal in the high-risk regions reflecting an equal exposure to risk factors [Wabinga et al. 2000].

During the last 30 years, there has been a decline or stabilization in the incidence of ESCC in Western countries [Keeney and Bauer 2006; Vizcaino et al. 2002; Pera 2003; Pera et al. 2005; Newnham et al. 2003a]. Over the same period, the age-standardized incidence of EAC has risen faster than any other malignancy in Western world. Though, EAC was a rare disease with the incidence $< 1:100,000$ before the 1970s, the incidence of EAC has now exceeded that of ESCC [Pohl and Welch 2005; Shaheen 2005; Lagergren 2005]. The incident rise is most significant in the white male population. It reaches 5 / 100,000 for white male in US and 8 -12 / 100,000 in the highest incident countries of Australia and the UK [Newnham et al. 2003a; Kubo and Corley 2002, 2004; Bollschweiler et al. 2001; Lord et al. 1998; Newnham et al. 2003b; Devesa et al. 1998; Registry 2000]. The age distribution of EAC peaks at 50 - 60 years and the male:female ratio is between 2:1 and 12:1 [Botterweck et al. 2000].

1.6.2 Etiology

ESCC is associated with many environmental factors including diet rich in preserved or pickled food, lack of fresh fruit and vegetables, vitamin and mineral deficiencies, and a thermal effect of hot food and beverages. Alcohol intake and smoking are also strong risk factors for ESCC [Farhadi et al. 2005; Bahmanyar and Ye 2006; Boeing et al. 2006]. Ethnic, obesity, esophageal sphincter-relaxing drugs, smoking and alcohol consumption have all been convicted as etiological factors in EAC [DeMeester and DeMeester 2000; DeMeester 2006; Lagergren et al. 2000; Lagergren and Jansson 2006; Lagergren et al. 1999a]. Cohort studies showed that gastroesophageal reflux and Barrett's disease represent causal factors for EAC [Solaymani-Dodaran et al. 2004; Lagergren et al. 1999b].

1.6.3 Prognosis

The prognosis of ESCC and EAC is poor and the overall tumor-specific lethality rate reaches up to 95 % [Lagarde et al. 2006]. Female appears to have better outcomes than male. The 5-year survival rate ranges from 5 % to 20 % for the patients undergoing operations with curative intent. Tumors in the upper esophagus associated with high operative risks. The immediate surgical results are consistently worse for ESCC than for EAC [Siewert and Ott 2007; Alexandrou et al. 2002; Abunasra et al. 2005]. This might be due to the fact that ESCC often existed in the mid or upper esophagus and is associated with other comorbidities such as age, chronic respiratory disease, liver disease and poor nutrition.

Chapter 2

Aim of Study

*H*yaluronan plays an important role in modulating cell phenotypes such as cell motility, cell-cell and cell-matrix adhesion, cell proliferation and differentiation. Elevated hyaluronan levels in the cancer epithelium and peritumoral stroma are thought to promote tumor progression.

HAS isoforms, HAS1, HAS2 and HAS3v1, are shown to be transmembrane proteins and in charge of extracellular HA synthesis. HAS3v2 is a smaller splicing variant of HAS3 that has been described in cultured human keratinocytes but has not been studied with respect to function yet.

Therefore, the following questions were addressed in this Ph.D thesis:

- What is the subcellular localization of HAS3v2 in comparison to HAS3v1?
- Does HAS3v2 have enzymatic activity?
- Does HAS3v2 expression alter the cellular phenotype of cancer cells *in vitro* and *in vivo*?
- Is HAS3v2 expressed in human esophageal cancer patients?

Chapter 3

Material and Methods

3.1 Materials

4-Methylumbelliferone	Sigma-Aldrich, Munich
Acrylamide 40 %	BioRad, Munich
Ammonium persulfate (APS)	BioRad, Munich
DMEM cell culture medium	Gibco-Invitrogen, Karlsruhe
Hoechst 33324	Sigma-Aldrich, Munich
Image-iT LIVE Plasma Membrane marker	Invitrogen, Karlsruhe
ER Tracker red	Invitrogen, Karlsruhe
EndoFree Plamid Maxi Kit	Qiagen, Hilden
PageRule Prestained Protein Ladder	Fermentas, St.leon-Rot
Poly-L-Lysine	Sigma-Aldrich, Munich
Pronase	Sigma-Aldrich, Munich
Protaminsulfate	Sigma-Aldrich, Munich
RPMI 1640 cell culture medium	Sigma-Aldrich, Munich
<i>Streptomyces</i> Hyaluronidase	Sigma-Aldrich, Munich
Quantitect reverse transcription Kit	Qiagen, Hilden
CyQUANT NF Cell Proliferation Assay Kit	Invitrogen, Karlsruhe
Platinum SYBR Green qPCR supermix -UDG w/ROX	Invitrogen, Karlsruhe
Tri-Reagent	Sigma-Aldrich, Munich
Vectashield Antifade Mounting Medium	Vector Laboratories, CA, USA
Vitrogen 100	Collagen Corp, Palo Alto, CA.USA
Whatman-Paper	Schleicher und Schuell, Maidstone,England
PVDF-Membrane	Bio-Rad Laboratories, Hercules, CA, USA

3.2.2 Generation of competent *E. coli* cells

E. coli were grown in 1 liter SOB medium at 37 °C and harvested (4000 × g, 20 min, 4 °C), when the OD 600 value of the culture reached 0.5 - 0.8. Cells were gently resuspended in 40 ml ice-cold TB buffer (10 mM Pipes, 55 mM MnCl₂, 15 mM CaCl₂, 250 mM KCl), incubated on ice for 20 min and again sedimented (4000 × g, 20 min, 4 °C). Cells were gently resuspended in 20 ml ice-cold TB buffer and DMSO was added with gentle swirling to a final concentration of 7 %. After 10 min incubation on ice, cells were dispensed in 0.1 ml aliquots, chill-frozen in liquid nitrogen and stored at -80 °C.

3.2.3 Transformation of *E. coli*

An aliquot of 0.1 ml competent cells was mixed with 2 μl ligation reaction mixture, incubated on ice for approximately 30 min, shocked at 42 °C 30" and immediately transferred onto the ice. Then, 0.5 ml warm LB-medium (37 °C) was

added to the cells and the mixture was incubated for 1 h at 37 °C with vigorous shaking (250 rpm). Afterwards, transformed cells were transferred to LB-agar plates containing 50 µg/ml ampicillin.

3.2.4 Plasmid preparation

Colonies were picked and inoculated in 2.5 ml TB medium containing 50 µg/ml ampicillin and incubated overnight at 37 °C with vigorous shaking (250 rpm). After approximately 14 hours, 2 ml of the culture were pelleted (6800 × g, 2 min, 4 °C). The cell pellet was mixed with 400 µl lysis solution (0.2 N NaOH, 1 % SDS), immediately neutralized with 300 µl 7.5 M NH₄OAC and kept for 10 min on ice, to precipitate genomic DNA and proteins, then sedimented at 14000 × g for 10 min at 4 °C. The plasmid DNA was precipitated from the supernatant with 500 µl 2-propanol and pelleted (14000 × g, 30 min, 4 °C). Finally, the DNA pellet was washed with 70 % EtOH, dried and resuspended in 50 µl TE (10 mM Tris-HCl pH 8.0, 1 mM EDTA) supplemented with 50 µg/ml RNaseA.

For Maxiprep, a single colony was picked and inoculated in a primary culture of 3 ml TB medium (containing selection reagent accordingly) and incubated for approx. 8 h at 37 °C with vigorous shaking (250 rpm). Afterwards the initial culture was diluted 1:1000 into 250 ml selective TB medium and grown overnight. Bacterial cells were harvested by centrifugation (6000 × g, 15 min, 4 °C) and the purification of plasmid DNA was performed with QIAGEN Endofree Plasmid Maxi Kit according to manufacturer's protocol. DNA concentration was determined spectrophotometrically by absorption at the wavelength of 260 nm.

3.3 Cell culture

PT1590 cells, skin fibroblasts and HEK cells were kindly provided by Dr. Stoecklein, Dr. Reifenberger and Dr. Mielke, respectively. PT1590 cells were grown in RPMI 1640 medium (Invitrogen, Karlsruhe) containing 10 % fetal bovine serum (Invitrogen, Karlsruhe) and 1 % penicillin/Streptomyces (Invitrogen, Karlsruhe). HEK cells and skin fibroblasts were grown in DMEM medium (Invitrogen, Karlsruhe) supplied with 10 % fetal bovine serum and 1 % penicillin/Streptomycin solution. Culture medium for stable transfected HEK cells was supplemented with puromycin (Invitrogen, Karlsruhe) at 0.4 $\mu\text{g}/\text{ml}$ to maintain selection pressure. PT1590 and HEK cells were maintained as subconfluent monolayer cultures at 37 °C under a humidified 5 % CO₂ atmosphere. For passaging, cell layers were washed once with PBS (Invitrogen, Karlsruhe), detached by a short trypsinization with Trypsin- EDTA solution (0.5 g/L of trypsin (1:250) and 0.2 g/L of EDTA·4Na) and reseeded with the density of 5000 cells/cm² for skin fibroblasts and 2000 cells/cm² for PT1590 and HEK cells, accordingly.

3.4 RNA isolation and cDNA reverse transcription

Total RNA from cultured cells and tissues was isolated using either the RNeasy mini kit (Qiagen, Hilden) or TriReagent (Sigma-Aldrich, Muenchen). Before RNA isolation, the tumors from the xenograft model were homogenized by the Mixer Mill MM 200 (Retsch, Haan). The RNA concentration was determined by photometric measurement at 260 nm using Nanodrop-1000 (Peglab, Erlangen). Aliquots of total RNA (1 μg) were applied for cDNA synthesis using Quantitect reverse transcription kit (Qiagen, Hilden). These experiments were performed

according to the manufactures' protocols.

3.5 Realtime RT quantitative PCR (qPCR)

Relative mRNA expression levels were quantified by qPCR. PCR was performed using an ABI 7300 real time system (Applied Biosystems, Darmstadt) with Platinum SYBR green qPCR SuperMix-UDG kit (Invitrogen, Karlsruhe). The reaction mixture for each gene contained 10 μ l of Platinum SYBR green qPCR SuperMix-UDG, 5 μ l cDNA and 2.5 μ l of each primer (with final concentration of 10 pmol) in a final volume of 20 μ l. Glyceraldehyde- 3-phosphate dehydrogenase (GAPDH) was chosen as the endogenous control using the same reaction mixture and conditions. All PCR primer sequences were designed by Primer3 software (<http://frodo.wi.mit.edu/primer3/>) (listed in section 3.1). The PCR amplification condition was as the following: 50 °C for 2 min and 95 °C for 2min, and this was followed by 40 cycles at 95 °C for 30 s and then 60 °C for 30 s. During the last steps, a temperature gradient between 95 °C and 60 °C was created for the analysis of the dissociation curves. This post-PCR dissociation curve was used to monitor the quality of PCR. No template controls, substituting water for cDNA, and a negative reverse transcription were used in each run. Target gene expression was calculated for each sample relative to the housekeeping gene, GAPDH, using the $2^{-\Delta\Delta C_t}$ method as described [Dai et al. 2007].

3.6 Quantification of HA from extra-, peri-and intracellular compartments

HA from the extracellular, pericellular and intracellular compartments of cultured cells were isolated and quantified as previously described [Wilkinson et al. 2006]. 24 hours after changing medium, culture supernatant was harvested and used for determination of extracellular HA. Next, cells were gently washed in PBS, trypsinized and centrifuged at $1000 \times g$ for 5 min. The resulting supernatant was taken and HA determined in this fraction was defined as pericellular HA. Afterwards, the cell pellet was washed twice in PBS and centrifuged at $1000 \times g$ for 5 min. Aliquots from the cell pellets were collected to isolate total protein. The protein concentration, which mimics the total cell number, was then quantified by Bradford protein assay (Bio-rad, München) and used to normalize the HA concentration. The HA from the cell pellet represented the intracellular HA fraction. The culture medium, the trypsin supernatant and the cell lysate were then digested by papain (5 mg/ml) in 0.1 M Tris-acetate, 5 mM EDTA, 5 mM L-cysteine hydrochloride at pH 7.3 for 24 hours at 60 °C. After digestion, papain was then inactivated by heating to 100 °C for 20 min. The HA concentration was subsequently measured by a commercial HA ELISA test kit (Corgenix, Peterborough).

3.7 Cell proliferation

CyQUANT NF cell proliferation kit was used to measure the growth rate of PT1590 cells according to the manufacture's protocol. Briefly, PT1590 cells were seeded in a 96 well microplate at a density of 4000 cells per well. For

each condition, the cells were seeded as octuplicate. The CyQUANT NF dye reagent was diluted 1:500 in $1\times$ HBSS buffer (Hank's buffered salt solution included in the kit). For the measurement, the culture medium was removed and $100\ \mu\text{l}$ $1\times$ dye reagent was dispensed to each microplate well. Instead of the dye reagent, $100\ \mu\text{l}$ $1\times$ HBSS buffer was used as the background count. The microplate was then incubated at $37\ ^\circ\text{C}$ for 30 min. Fluorescence intensity of each sample was measured using a fluorescence microplate reader (excitation at 485 nm and emission at 530 nm). The cells were first allowed to adhere for 4 hours. The control value was therefore taken after 4 hours adhesion. 24 hours after seeded, the cell density was again measured and the proliferation rate was calculated with normalization to the 4-hour initial value.

3.8 Cell adhesion

PT1590 cells were trypsinized and washed two times with PBS before assessing the adhesion. The cells were resuspended to 1×10^6 cells/ml with culture medium containing 10 % FCS. Subsequently, the cells were seeded in 96-well plates ($100\ \mu\text{l}$ per well). After 15 minutes of incubation at $37\ ^\circ\text{C}$, the unattached cells were washed away by PBS buffer. The attached cells were then fixed and stained by crystal violet solution containing 50 % methanol for 5 min at $22\ ^\circ\text{C}$ and washed 6 times with $100\ \mu\text{l}$ ddH₂O. Finally, the cells were lysed by $100\ \mu\text{l}$ 2 % SDS. A UV spectrometric microplate reader was used to determine the absorption at 540 nm.

3.9 Cell growth kinetics

After trypsinization, cells were resuspended and seeded in 12-well plates at a density of 4000 cells per well. The cell number was determined by a Neubauer chamber at 1, 2, 3, 4, and 5 days after seeding. Before loading onto the Neubauer chamber, the cell suspension was mixed 1:1 with trypan blue to distinguish living and dead cells.

3.10 Intracellular HA staining & confocal imaging

Staining of intracellular hyaluronan was performed as previously described using a biotinylated hyaluronan-binding protein specific for hyaluronan [Evanko and Wight 1999]. Skin fibroblasts (2×10^5 per 6-well) were plated and grown on 22-mm² coverslips inserted into the wells for 24 hours in DMEM containing 10 % fetal bovine serum. Extracellular and pericellular hyaluronan was removed prior to fixation by incubating the cells with 2 U/ml *Streptomyces* hyaluronidase (Sigma-Aldrich, München) in culture medium at 37 °C for 60 min. Cells were fixed in 3.7 % paraformaldehyde in PBS for 10 min at 22 °C and then permeabilized with 0.5 % Triton X-100 for 10 min. Afterwards, cells were blocked with 1 % BSA in PBS for 1 hour at 22 °C. The biotinylated HABP was used at a concentration of 2.5 µg/ml in PBS containing 1 % BSA for 1 hour at 22 °C. The biotinylated HABP was further detected with Cy3-streptavidin. Nuclei were counterstained with Hoechst 33342 (Invitrogen, Karlsruhe) at 1 µg/ml in H₂O for 10 min at 22 °C. Coverslips were mounted with Antifade Mounting Medium (Vector Laboratories, CA, USA). Controls for specificity of the intracellular hyaluronan staining included digestion of the cells with *Streptomyces* hyaluronidase after permeabi-

lization and without permeabilization before adding biotinylated HABP.

For microscopic analysis, a Zeiss inverted LSM 510 META confocal laser fluorescent microscope (Carl Zeiss, Jena) with 63 ×/1.4 NA oil-immersion objective was used. Hoechst 33342 was excited by diode laser at 351 nm. Argon laser was used to excite Cy3 at 543 nm wavelength. The emission signals were collected through proper filters. All the images, including the negative controls, were taken under the same condition.

3.11 Vector construction of stable transfection

The pMC-EYFP-P vector was used for YFP-HAS fusion protein construction. As shown in figure 3.1, the CMV promoter drives the expression of YFP fusion protein as well as the selection marker, namely puromycin resistant gene (pAC). Human HAS2, HAS3v1 and HAS3v2 coding sequences were isolated from total RNA of human smooth muscle cells by RT-PCR with primers indicated in table 3.5. The PCR products of HAS2 and HAS3v1 are about 1.7 kb and HAS3v2 about 0.9 kb respectively. The multicloning site is located at the c-terminal of the YFP coding sequence. N-terminal YFP-HAS fusion protein coding sequences were constructed using the MluI and EcoRI restriction sites. All the coding sequences were controlled by sequencing.

3.12 Construction of stably transfected cell lines

HEK cells were grown until they reach 80 % confluency in monolayer culture (25 cm²). Then, HEK cells were splitted 1:4 24 hours before transfection. Cells

Figure 3.1: **Vector map of pMC-EYFP-P**

CMV promoter drives the expression of YFP fusion protein as well as the selection marker, namely puromycin resistant gene (pAC). The multicloning site is located at the c-terminal of the YFP coding sequence. Human HAS2, HAS3v1 and HAS3v2 coding sequences were isolated from total RNA of human smooth muscle cells by RT-PCR. N-terminal YFP-HAS fusion protein coding sequences were constructed using the MluI and EcoRI restriction sites.

Table 3.5: **Primers for YFP-HAS fusion protein construction**

were transfected with 1 μ g DNA using Effectene Transfection Reagent (Qiagen, Hilden) according to the manufacturer's instructions. Transfection efficiency was monitored by fluorescence microscopy after 24 hours. The transfection efficiency appeared to be between 20 - 90 % depending on the construct used. 30 hours after transfection, cells were appropriately seeded into d-150 (150 mm in diameter) tissue culture dishes. Subsequently, stably transfected cell clones were selected by 0.4 μ g/ml puromycin for 7 days. Stably expressing clones were then picked and reseeded in the 6-well in selection medium. For maintenance, the stable cell clones were cultured in selection medium.

3.13 Live-cell staining and imaging

The live-cell-imaging chamber (Ibidi, Martinsried) was coated with 200 μ l poly-L-lysine (25 μ g/ml) for 2 hours at 22 °C under sterile condition. 24 hours before microscopy, the HEK cells were seeded in a live-cell-imaging chamber at a density of 5000 cells/cm². Before microscopy, the culture medium was exchanged by CO₂-independent medium (Invitrogen, Karlsruhe). An epifluorescent microscope and a 40 \times oil immersion objective were used for imaging. The objective

holder was pre-warmed to 37 °C before usage.

To study subcellular localization, cells were stained with either Image-iT LIVE plasma membrane labeling Kit (Invitrogen, Karlsruhe) or ER-Tracker Red (Invitrogen, Karlsruhe) according to the manufacturer's protocol.

3.14 HAS enzymatic capture assay

Enzymatic activity of cellular HAS isoforms was determined in microsomal preparations. Briefly, cells were sonicated in microsome buffer (PBS containing 0.01 % SDS, 1 mM PMSF, 1mM EDTA, 20 mM DTT) for 12 min and were vortexed in between. The plasma membrane and nuclear fragments were then sedimented by centrifugation at $10,000 \times g$ at 22 °C for 20 min. Supernatants were collected for additional centrifugation at $100,000 \times g$ for 1 hour at 4 °C. The pellet, which is enriched in microsomes, was resolved in 200 μ l microsome G buffer (PBS containing 0.01 % SDS, 1 mM PMSF, 1 mM EDTA, 20 mM DTT with 30 % Glycerol) and stored at -20 °C for overnight. Microsomes were mixed 1:1 with HAS buffer (PBS containing 2 mM $MgCl_2$, 1 mM UDP-Glucosamine, 1mM UDP-Glucuronic acid, 1 mM PMSF, 1 mM EDTA, 1 mM DTT) and incubated at 37 °C for 24 hours. As control, half of the microsomal solution was treated with *Streptomyces* hyaluronidase for 2 hours at 37 °C to remove the HA from the HA-HAS complex. Subsequently, 1 μ g of biotinylated HABP was added to the microsomes with/without *Streptomyces* hyaluronidase treatment and incubated at 37 °C for 1 hour. Streptavidin-agarose beads were added to each vial and incubated at 22 °C for 1 hour. The agarose beads were pelleted by centrifugation and washed two times with PBS. Then, protein lysis buffer (receipt shown in section 3.15.1) was added to the agarose beads to elute proteins from the

beads. The protein lysate was collected by centrifugation and denatured for 5 min at 95 °C prior to further analysis.

Microsomal preparations from YFP, YFP-HAS3v1 and YFP-HAS3v2 stably trasfected HEK cells were used for HAS enzymatic activity assay. Protein lysates were run on 10 % SDS-PAGE gels according to routine procedures. After blotting, the nutrocellulose membranes were blocked by blocking buffer (recipe in section 3.1) at 22 °C for 1 hour. Then, the membranes were incubated with the YFP antibody (Clontech, France) dilluted 1:4000 in blocking buffer with gentle agitation overnight. Membranes were washes three times with $1 \times$ TBST for 5 minutes each and further incubated with IRDye 800CW Goat Anti-Mouse IgG (Licor, Bad Homburg) with 1:5000 dilution in blocking buffer at 22 °C for 1 hour. Finally, membranes were washed 6 times with $1 \times$ TBST for 5 minutes each and images were taken and analyzed by Odyssie Imager (Licor, Bad Homburg).

3.15 Immunoblotting

Recipes of buffers and gels used for immunoblotting are listed in section 3.1

3.15.1 Protein isolation from cultured cell

Cell lysis was performed with lysis buffer (100 mM Tris-HCl, pH 6.8, 2 % Glyc-erol, 2 % SDS, 10 mM DTT, 0.7 M Urea, 10 mM EDTA, 1 mM PMSF, 0.02 % bromphenol blue). Cell lysates were homogenized by sonification for 15 min. Subsequently, samples were denatured at 95 °C for 5 min. Protein sample were then stored at -20 °C.

3.15.2 SDS-Polyacrylamide Gel Electrophoresis (PAGE) & Coomassie staining

Protein lysates were run on 10 % SDS-PAGE gels according to routine procedures.

The SDS gel was stained by Pageblue protein stain solution (Fermentas, St. Leon-Roth) according to the manufacturer's protocol. Briefly, the gel was washed 3 times with 100 ml ddH₂O for 10 min each to wash SDS away. Then, the gel was soaked in the pageblue protein stain solution for 1 hour with gentle agitation. To remove the background staining, the gel was rinsed with ddH₂O for 5 min before imaging.

3.15.3 Blotting

Proteins were electrophoretically transferred from the gel to nitrocellulose membranes by the semi-dry method. Briefly, 3 Whatman papers were soaked in transfer buffer and then stacked on the cathode side of the gel. Then, the nitrocellulose membrane was shortly rinsed in the transfer buffer and carefully stacked on the anode side of the gel. Another 3 Whatman paper were stacked on top of the membrane after soaking in transfer buffer. Subsequently, the stack was placed between two graphite plates and the trans-membrane blotting was performed with constant volt 12 V for 1 hour.

Table 3.6: **Antibody dilution ratios**

3.15.4 Immunodetection of protein

The nitrocellulose membrane was blocked in blocking buffer with gentle agitation for 1 hour at 22 °C. Afterwards, the first antibody was diluted in blocking buffer. The membrane was incubated in the first antibody solution on the shaker for either 1 hour at 22 °C or overnight at 4 °C. Then, the membrane was washed three times in 1 × TBS containing 0.1 % Tween 20 for 5 min each. After washing, the membrane was soaked for 1 hour at 22 °C with the secondary antibody. The secondary antibody was diluted with blocking buffer under corresponding ratio. The antibody dilution ratios are listed in table 3.6. The blot membrane was then immersed 5 times for 3 min in 1 × TBS containing 0.1 % Tween 20. Finally, the image was taken and analyzed by Odyssey Imager (Licor, Bad Homburg).

3.16 Lentiviral transduction

3.16.1 Overexpression vector cloning

Lentiviral vectors can deliver large cDNAs to a variety of dividing and non-dividing cells, including terminally differentiated mammalian cells e.g. neurons, lymphocytes and macrophages. Due to the lack of toxicity and immune response, lentiviruses became a very attractive tool for gene delivery and possibly further use for human gene therapy. The safety of the lentiviral vectors has been improved with the generation of self-inactivating vectors and a minimal packaging system. For this study, a vector system constructed by Prof. Hanenberg was used [Dai et al. 2007]. The HIV envelope glycoprotein was replaced by VSV-G. To minimize the amount of HIV coding regions present in the packaging system, a second generation of the packaging system was developed with extensive deletions of the viral genome. This 2nd generation packaging system contains only the gag, pol, tat, and rev genes of HIV-1 and lacking all accessory genes, since accessory genes (vpr, vpu, vif and nef) are not required for efficient production of viral particles. The 2nd generation lentivirus packaging system contains 3 plasmids. The pVSVG is the plasmid that encodes the envelope protein. pCD/NL-BH is the packaging plasmid and pCL1 was used as the transfer plasmid. The pCL1 is used as the mock vector, which is characterized by the EGFP expression (shown in figure 3.2). pCL1mcs was digested by restriction enzyme XhoI and EcoRI. The cDNA of human HAS3v2 was obtained by RT-PCR using total RNA from human smooth muscle cells with the following primers: XhoI-HAS3v2-F: AAAC TCGAGATGCCGGTGCAGCTGACGACAG and EcoRI-HAS3v2-R: AAAGAATTCTCACTGCTCTCTAGAAACGTGG. Then, the human HAS3v2 cDNA was cloned into the multiple cloning site of pCL1mcs

to achieve the new plasmid named pCL1mcs-HAS3v2. The coding sequence of HAS3v2 in the pCL1mcs-HAS3v2 was confirmed by sequencing.

3.16.2 Lentivirus production

The day before transfection, HEK293T cells were seeded into d-100 (100 mm in diameter) cell culture dishes at a density of $2.5 - 3 \times 10^6$ cells per plate. DMEM medium supplied with 10 % heat-inactivated FCS (v/v) (PAN biotech, Aidenbach) and $1 \times$ penicillin/Streptomycin (100 U/ml of penicillin, 100 μ g/ml of Streptomycin) was used for virus production.

Transfection was carried out using polyethylenimine (PEI) (Sigma-Aldrich, München) method. 5 μ g of transfer vector, either pCL1 mock or HAS3v2 over-expression vector pCL1mcs-HAS3v2, 5 μ g of packaging plasmid (pCD/NL-BH) and 5 μ g of envelope plasmid (pVSVG) were diluted with DMEM medium to a final volume of 2 ml in a sterile reaction tube. 45 μ l of 1 mg/ml PEI was added to the vector mix, and then thoroughly vortexed. Afterwards, the mixture was incubated for 20 min at 22 °C under sterile condition to allow the DNA-PEI complex form. The 293T culture medium was replaced with 4 ml DMEM with 10 % heat-inactivated FCS and $1 \times$ Pen/Strep solution. Subsequently, the DNA-PEI complex was added drop-wise to the 293T. After gentle mixing, the 293T cells were incubated for 16 hours in the humidified incubator at 37 °C and 5 % CO₂. Then, the transfection medium was changed to complete medium containing 10 mM sodium butyrate to induce the CMV promotor activity. 6 hours after induction, the culture medium was refreshed with 5 ml IMDM medium (Sigma-Aldrich, Muenchen) supplied with 10 % heat-inactivated FCS and $1 \times$ Pen/Strep solution. The virus containing IMDM medium was harvested and filtered through a 0.45 μ m sterile filter 24 hours after induction. Then, the medium was either

Figure 3.2: **Vector map of pCL1mcs**

The multicloning site is located after SFFV U3 fragment. Human HAS3v2 coding sequences was isolated from total RNA of human smooth muscle cells by RT-PCR and constructed using the XhoI and EcoRI restriction sites. CMV promoter drives the expression of either EGFP (mock control) or HAS3v2.

used for transduction directly or stored at -80 °C after aliquots.

3.16.3 Lentivirus titration

The RETRO-TEK HIV-1 p24 Antigen ELISA (Zeptometrix , USA) is an enzyme linked immunoassay used to detect Human Immunodeficiency Virus Type 1 (HIV-1) p24 antigen. Microwells are coated with a monoclonal antibody specific for the p24 gag gene product of HIV-1. Viral antigen in the specimen specifically bound to the immobilized antibody during incubation. The captured antigen then detected with a high-titer human anti-HIV-1 antibody conjugated with biotin. Following a subsequent incubation with Streptavidin-Peroxidase, color develops as the bound enzyme reacts with the substrate. Resultant optical density is proportional to the amount of HIV-1 p24 antigen present in the specimen.

3.16.4 Lentiviral transduction

Both skin fibroblasts and PT1590 cells were grown 50 % - 70 % confluence before lentiviral transduction. DMEM medium was used for skin fibroblast while PT1590 cells were transduced in RPMI 1640 medium. Both medium were supplied with 10 % heat-inactivated FCS and 1 × Pen/Strep solution. For transduction, equal titers of virus were thawed on ice and diluted in the appropriated medium with 4 µg/ml protamine sulfate. Protamine sulfate is a small, positively charged molecule that binds to cell surfaces, neutralizes surface charge and thereby greatly enhances transduction by lentiviruses. The cell culture medium was changed 24 hours and 96 hours after transduction.

3.17 Xenograft of EAC cells in nude mice

3.17.1 Tumor inoculation

10 weeks-old NMRI nu/nu mice were used for subcutaneous tumor formation after xenografting of PT1590 cells. Five days after lentiviral transduction, cell injections were performed with 100 μ l cell suspension containing 1×10^6 cells. Cells were harvested, counted and washed two times using PBS. Then, the pellets were resuspended in PBS. After cleaning the skin with alcohol, tumor cell suspensions were injected s.c. using an 1 ml insulin syringe into both flanks, and the mice were monitored for 35 days after xenografting. The animal experiments were approved by the local animal facility and the Landesamt fr Natur, Umwelt und Verbraucherschutz, NRW.

3.17.2 Growth curve

Starting at 14 days after injection, tumor diameters were measured with digital calipers every 3 or 4 days. The tumor volume in mm^3 was calculated by the formula: $Volume = (Length \times width \times height) \times \pi/2$. The tumor growth was monitored by determining of the cumulative tumor volume until harvesting. The wet weight of tumors were measured at harvesting.

3.17.3 Immunohistochemistry

The mice were sacrificed by asphyxiation with CO_2 and the tumors were dissected. Part of the tumors were embedded in OCT Tissue Tek (Sakura Finetek, Netherlands), frozen at -40°C isopentane and stored at -80°C . Cryostat CM

3050 from Leica Instruments was used to cut 2 μm thick cryosections. Sections were loaded on Superfrost slides (Fisher Scientific, USA) and stored at -20°C .

For immunohistochemistry, the cryo-sections were blocked with 10 % fetal calf serum and 1 % bovine serum albumin for 1 hour at room temperature. For hyaluronan staining, the slides were subsequently incubated with biotinylated HAbP (2 $\mu\text{g}/\text{ml}$; Seikagaku, Tokyo, Japan) at 4°C overnight. After three washes with phosphate-buffered saline (PBS), the sections were incubated with avidin-biotin peroxidase (Sigma, St. Louis, MO), and the color was developed with 3,3'-diaminobenzidine (DAB; Sigma). Nuclei were stained with hemalaun solution (Merck, Darmstadt, Germany). As a negative control, sections were incubated with *Streptomyces* hyaluronidase (ICN, Costa Mesa, CA) at a concentration of 2 U/ml (1 hour, 37°C) before HA staining. Proliferation marker, Ki67, was stained using rabbit anti-human/mouse ki67 antibody (1:25; Novus Biologicals, Littleton, CO) and sheep anti-rabbit IgG (peroxidase-conjugate, 1:50; Sigma-Aldrich, Steinheim, Germany). DAB detection was as described for HA staining

The images were taken at $100\times$ magnification with a Leica Upright Microscope (Leica, Wetzlar).

3.18 Statistical analysis

Quantitative results are presented as mean values \pm standard error of the mean (SEM). Data sets were compared either by unpaired T-test or one way ANOVA using the software PRISM Graphad 5.0. $p\text{ value} < 0.05$ was regarded as statistically significant.

Chapter 4

Results

4.1 *In silico* enzymatic activity analysis of HAS3v2

4.1.1 Human HAS3 splicing variants: HAS3v1 & HAS3v2.

There are three mammalian hyaluronan synthase isoforms, namely HAS1, HAS2 and HAS3. The structures of these three genes are evolutionary conserved in mammalian species. Human HAS3 has two splicing variants: HAS3v1 and HAS3v2. As shown in figure 4.1 A, both splicing variants share the first two coding exons. The coding sequence on the last exon of HAS3v1 is different and longer than the one of HAS3v2. However, HAS3v2 spans over a longer part on the genome. The predicted protein topologies of both splicing variants are shown in figure 4.1 B. The prediction is based on hydropathy plots [Weigel et al. 1997]. Accordingly, HAS3v1 is predicted to have seven transmembrane domains, while HAS3v2 has only two. The intracellular loop between the 2nd and the 3rd transmembrane domain (66-383AA) of HAS3v1 is predicted to be the catalytic domain, through which hyaluronan is synthesized. The putative catalytic domain is based on the *in silico* evolutionary homologous analysis. HAS3v2 contains part of the catalytic domain (66-246AA) followed by a 35AA long c-terminal tail that is unique for HAS3v2..

4.1.2 Glycosyl transferase 2 domain.

Whether HAS3v2 contains a putative catalytic center was tested *in silico* by pfam (<http://pfam.sanger.ac.uk/>). Pfam is a database of protein families that includes their annotations and multiple sequence alignments generated using hidden Markov models. As shown in figure 4.2 A, the active glycosyl transferase

Figure 4.1: **Genomic and topological structure of human HAS3 isoforms**

(**A**): genomic structure of human HAS3 splicing variants; (**B**): predicted topological protein structure of HAS3 splicing variants. The orange intracellular part of HAS3v1 and HAS3v2 are identical in AA sequence. The blue part on the c-terminal of HAS3v2 indicates its unique AA composition.

Figure 4.2: *In silico* prediction of glycosyl transferase activity of HAS3v2

(**A**): functional domain prediction using pfam. Glycosyl transferase 2 domain (red block) is detected from HAS3v1 and HAS3v2 (grey line indicates the AA sequence).; (**B**): 3D protein structure prediction of the active center of HAS3v1 and HAS3v2. The green overlay indicates the identical structure between HAS3v1 and HAS3v2. The yellow part is unique for HAS3v1 and pink part for HAS3v2 respectively.

2 domain was predicted for the amino acid sequence between AA 88 to AA 124 of both HAS3v1 and HAS3v2. This domain is localized within the predicted catalytic centers of HAS3v1 and HAS3v2. The glycosyl transferase 2 domain is the only enzymatic domain found in HAS3v1. Further, HAS3v1 is known to be an active hyaluronan synthase.

In addition, 3D protein structures of both the catalytic loop of HAS3v1 and the c-terminal intracellular tail of HAS3v2 were simulated using the software hhpred (<http://toolkit.tuebingen.mpg.de/hhpred/>). These two protein structures

were overlapped to analyze the structural similarity. As shown in figure 4.2 B, the overlap between the catalytic centers from HAS3v1 and HAS3v2 is indicated by the green color. Of note, the glycosyl transferase 2 domain is localized on this green overlap as well. The pink part is unique for HAS3v2 while the yellow part only exists in HAS3v1. Therefore, HAS3v2 might also function as active hyaluronan synthase, despite its truncated structure and the lack of 5 transmembrane domains compared to HAS3v1.

4.2 Subcellular localization of human HAS3v2

4.2.1 Localization of HAS3v2 as analyzed by YFP-HAS fusion protein.

Figure 4.3: **Schematic structure of YFP-HAS fusion protein**

(A): Genomic structure of human HAS3; (B): Scheme of YFP-HAS fusion protein

To address the subcellular localization of HAS3v2, YFP fusion proteins were constructed. Figure 4.3 B shows the scheme of the plasmids. The CMV promoter was used to drive the expression of YFP-HAS fusion proteins. RT-PCR

Figure 4.4: **HA quantification of extracellular secretion after YFP-HAS transfections**

After transfection of HEK 293 cells, HA concentration was determined from cell culture supernatant and normalized to cellular protein. In addition, 4-MU was used to inhibit HA synthesis. Data are normalized to YFP Control. white bar: without 4-MU; black bar: with 0.5 mM 4-MU; representative result out of triplicate experiment

was performed to obtain the full-length coding sequences of human HAS2, HAS3v1 and HAS3v2 from total RNA of human smooth muscle cells. Afterwards, these sequences were cloned to fuse onto the 3' end of YFP coding sequence. The YFP-HAS chimera were over-expressed by transfecting the target cell hosts. The mock YFP expression vector served as control.

4.2.2 Transfection of YFP-HAS2 and YFP-HAS3 causes increased HA in culture medium.

HEK 293 cells were selected as the host, in which YFP, YFP-HAS2, YFP-HAS3v1 and YFP-HAS3v2 stably overexpressed. The stable cell clones were selected by puromycin beginning 24 hours after transfection. Colonies were picked after 7 days of selection. The culture medium from these stable cell

Figure 4.5: **Subcellular localization of YFP-HAS fusion proteins**

HEK 293 cells were transfected with YFP-HAS expression vectors and selected by promycin. After isolation of stable clones, the expression of YFP fusion proteins were monitored by fluorescence microscopy. Upper panel: phase contrast; lower panel: YFP channel. White arrows indicate the microvilli structure on plasma membrane. Magnification: 400 ×

lines were collected for measuring HA secretion within 24 hours after medium change. As is shown in figure 4.4, overexpression of YFP-HAS2 and YFP-HAS3v1 induced extracellular HA up to 7 fold within 24 hours compared to YFP mock control. The overproduction of HA could be attenuated by a specific inhibitor of hyaluronan synthases, namely 4-methylumbelliferone (4-MU). This indicates that the YFP-HAS fusion proteins are active. However, overexpressing YFP-HAS3v2 in HEK cell did not lead to increased HA secretion of HA in the cell culture medium.

4.2.3 The subcellular localization of HAS3v2 is different from HAS3v1 and HAS2.

The sub-cellular expression patterns of the YFP-HAS fusion proteins were examined by fluorescent microscopy. As shown in figure 4.5, the YFP mock con-

struct shows ubiquitous YFP signal throughout the cell, as well as in the nucleus. The expression patterns of YFP-HAS2 and YFP-HAS3v1 are similar. Importantly, these two YFP fusion proteins are expressed at the circumstance of the cell indicating the plasma membrane localization. In addition, increased microvilli structures can also be observed (indicated by white arrow in figure 4.5). YFP-HAS2 and YFP-HAS3v1 were also detected in cytosol. However, the fluorescent signal of YFP-HAS3v2 was localized in the cytosol characterized by a network-like structure. Furthermore, there was no clear signal surrounding the cell, suggesting that the YFP-HAS3v2 may not expressed in the plasma membrane.

4.2.4 Subcellularly, HAS3v2 does reside the ER and Golgi.

A plasma membrane marker was introduced to evaluate whether HAS3v2 is localized in the plasma membrane. As shown in figure 4.6 A, in case of YFP-HAS3v1 and YFP-HAS2 the YFP signal surrounding the cell overlapped with the cy3 signal from the plasma membrane marker. However, there was no overlap between the YFP signal from YFP-HAS3v2 and the plasma membrane marker. This illustrates that, unlike HAS2 and HAS3v1, HAS3v2 is not present in the plasma membrane. The YFP mock control shows ubiquitous signal inside the cell.

Endoplasmic reticulum (ER) has an interconnected-network structure in the cell, which is similar to the YFP-HAS3v2 expression pattern. HAS3v2 also has two predicted hydrophobic transmembrane domains. Therefore, it is suspected that HAS3v2 might be present in the ER. Cy3-ER marker was utilized for the co-localization experiment. In figure 4.6 B, the YFP mock control showed overlap with the ER-Golgi marker, which was expected due to the ubiquitous localization

Figure 4.6: Co-localization analysis using plasma membrane and ER marker

(A): Cy3 conjugated plasma membrane marker; (B): Cy3 conjugated ER marker. Magnification: 400 ×

inside the cell. Also, partial overlap of the ER marker and the accumulated intracellular YFP signal from YFP-HAS2 and YFP-HAS3v1 was observed. The phase contrast pictures revealed that the condensed intracellular YFP signal of both YFP-HAS2 and YFP-HAS3v1 can be tracked to the golgi apparatus. This might be explained by the fact that both HAS2 and HAS3v1 are processed in the golgi and further transported to the plasma membrane. Importantly, the subcellular interconnected-network-like expression pattern of HAS3v2 showed a complete overlap with the ER marker, which suggested that HAS3v2 is indeed localized in the ER.

4.3 Biological function of HAS3v2

4.3.1 Overexpression of HAS3v2 causes a increase of intracellular hyaluronan.

Due to the ER localization of HAS3v2, HA-ELISA was performed in order to quantify the extracellular, pericellular as well as the intracellular hyaluronan of YFP-HAS3v2 compared to YFP transfected cells. For the extracellular and pericellular hyaluronan, there were no significant differences between YFP-HAS3v2 and YFP mock. Yet, there was significantly more intracellular hyaluronan from YFP-HAS3v2 compared to YFP mock (figure 4.7 A).

Subsequently, the HAS3v2 was overexpressed in human skin fibroblast using the lentiviral vector. Five days after transduction, the samples were collected for quantifying hyaluronan in the three different cellular compartments. As shown in figure 4.7 B, significant induction of intracellular hyaluronan occurred in response to the overexpression of HAS3v2 compared to pCL1 mock.

Figure 4.7: **HAS3v2 increases intracellular HA.**

Extra-, peri- and intracellular HA from stably transfected HEK cells (**A**) and lentiviral transduced skin fibroblasts (**B**) were quantified by HA ELISA. Immunocytochemical analysis of intracellular HA from lentivirally transduced skin fibroblasts (**C**): pCL1 mock, permeabilized (**I**); overexpression of HAS3v2, permeabilized (**II**); overexpression of HAS3v2, non-permeabilized (**III**); overexpression of HAS3v2, *streptomyces* hyaluronidase digestion after permeabilization (**IV**). The HAS3v2 overexpression leads to a new localization pattern of intracellular HA (white triangle) compared to pCL1 mock (white star).

No statistically significant differences of extracellular and pericellular hyaluronan were observed between pCL1 mock and the overexpression of HAS3v2.

Beside the HA quantification by ELISA, intracellular hyaluronan was stained using the biotinylated HABP (HA binding protein). Skin fibroblasts were transduced either by pCL1 mock or HAS3v2 lentivirus prior to intracellular HA staining. Skin fibroblasts were fixed on the glass cover slides five days after transduction with either pCL1 mock (I) or HAS3v2 overexpression (II) lentiviruses. Then, the cells were digested by hyaluronidase before permeabilizing the cell membrane. This procedure removes the extra- and pericellular hyaluronan. Afterwards, the cells were stained by biotin-HABP and cy3-streptavidin. Hoechst 33342 is used to indicate the cell nuclei. Images were taken by using confocal laser microscopy. As shown in figure 4.7 C, overexpression of HAS3v2 (II) in human skin fibroblast led to enhanced intracellular HA compared to pCL1 (I) mock control. To prove the specificity of intracellular staining, two negative controls were included. The HAS3v2 overexpressing skin fibroblasts were stained either without permeabilization of the cell membrane (III) or after *streptomyces* hyaluronidase digestion of permeabilized cells (IV). Both negative controls showed no positive staining, which confirms the specificity of the stainings in (I) and (II).

4.3.2 HAS3v2 might be an active intracellular hyaluronan synthase.

Intracellular HA may arise from both endocytosis and *de novo* synthesis [Evanko and Wight 1999]. Further, intracellular HA also accumulates on the outer membrane of ER. Therefore, HAS3v2 might be a promising candidate for an intra-

cellular hyaluronan synthase. The modified HAS enzymatic capture assay was used to investigate whether HAS3v2 can mediate HA synthesis [Kynosseva and Weigel 2007]. As illustrated in figure 4.8 A, hyaluronan synthases form a complex with HA after synthesis. Biotinylated HABP was used to bind the HA of the HA-HAS complex so that the whole complex (bHABP-HA-HAS) can be co-immunoprecipitated by streptavidin conjugated agarose. As negative control, *Streptomyces* hyaluronidase was used to digest the HA from the complex before incubating with biotinylated HABP. After digesting the HA by hyaluronidase, hyaluronan synthases can not bind to the agarose anymore. As a result, no co-immunoprecipitated HAS can be detected.

Microsomes are the raw membrane fraction of the cells, which contains mainly ER and golgi apparatus. Microsomes, which were isolated from YFP, YFP-HAS3v1 and YFP-HAS3v2 transfected HEK 293 cells were incubated with UDP-glucuronic acid and UDP-acetylglucosamine overnight. Subsequently, the modified HAS enzymatic capture assay was performed as described above. The proteins linked to the agarose were washed out by protein lysis buffer for western blot. YFP antibody was used to detect the YFP epitope of the fusion proteins. The result is shown in figure 4.8 B. YFP is not immunoprecipitated indicating the specificity of the experiment. However, both YFP-HAS3v1 and YFP-HAS3v2 were co-precipitated. The YFP-HAS3v1 fusion protein has a predicted molecular weight of 90 kDa, which has in line with the signal of the immunoblot shown in figure 4.8 B. The double bands formed in case of YFP-HAS3v1 might be due to posttranslational modifications. This also suggests that c-terminal truncation of HAS3v1 does not affect its enzymatic activity. The molecular weight of YFP-HAS3v2 fusion protein is 58 kDa, which was also detected on the YFP westernblot after the enzymatic capture assay. The co-precipitations were prevented by digesting the HA-HAS complex with hyaluronidase as a negative

Figure 4.8: **HA-HAS3v2 complex is detected by modified HAS enzymatic capture assay**

(A): Scheme of modified HAS enzymatic capture assay. Further details are given in section 3.14;

(B): Immunoblot analysis of the YFP epitope with the protein samples from modified enzymatic capture assay. Microsomes from YFP (1), YFP-HAS3v1 (2, 3) and YFP-HAS3v2 (4, 5) stably transfected HEK 293 cells were used for the assay. Hyaluronidase digestion (lane 2, 4) was performed prior to addition of biotinylated HABP.

control. This indicates that HAS3v2 might be an active hyaluronan synthase.

4.4 HAS3v2 in esophagus adenocarcinoma

4.4.1 Upregulation of HAS3v2 in esophageal adenocarcinoma (EAC)

Biopsies were collected from patients who suffered from either esophageal squamous cell carcinoma (ESCC) or esophageal adenocarcinoma (EAC). After the surgical intervention, samples were stored immediately in liquid nitrogen. Total RNA was isolated and the relative expression levels of hyaluronan synthase isoforms were quantified by realtime RT qPCR. All the data were then normalized to the average of the mucosa group. As shown in figure 4.9, HAS3v1 is upregulated in ESCC compared to mucosa and other HAS isoforms remain constant. In contrast, only HAS3v2 was significantly upregulated in the ADC group compared to mucosa.

4.4.2 In EAC, the expression level of HAS3v2 is positively correlated with the TNM tumor staging.

HAS3v2 is upregulated in EAC compared to mucosa. Therefore, it appeared important to examine whether the induction of HAS3v2 was correlated with tumor progression. Tumor stage and grading were classified by routine histopathologic assessment according to the UICC (Union Internationale Contre le Cancer) Classification for Malignant Tumors. Then, the relative expression levels of HAS3v2 from each tumor sample was plotted against the respective its TNM

Figure 4.9: **Expression level of HAS isoforms in human ESCC and EAC compared to mucosa**

mRNA expression was determined by RT-qPCR from tumor material removed during surgery. As control, healthy mucosal tissue from the circumstance of the excised tumors was used. One-way ANOVA method was used for statistic analysis. n=13 for mucosa control, 12 for ESCC and 40 for EAC, respectively.

Figure 4.10: **HAS3v2 expression level is positively correlated with EAC TNM tumor staging**

mRNA expression was determined by RT-qPCR from tumor material removed during surgery. As control, healthy mucosal tissue from the circumstance of the excised tumors was used. Correlation coefficient method was used for statistic analysis. n=5 for T1, 16 for T2, 17 for T3 and 2 for T4, respectively.

tumor staging. As is shown in figure 4.10, HAS3v2 expression correlates with increasing tumor staging. Correlation coefficient method was used for statistic analysis.

4.5 Functional analysis of HAS3v2 in EAC cells *in vitro*

4.5.1 Overexpression of HAS3v2 in EAC cells leads to a proliferative phenotype *in vitro*.

HAS3v2 was strongly upregulated in EAC. Therefore, the functional analysis of HAS3v2 was performed in EAC cell line, i.e. PT1590. PT1590 cells were transduced with either pCL1 mock or HAS3v2 overexpression lentivirus. The

proliferation assay was performed 5 days after transduction. As shown in figure 4.11 A, overexpression of HAS3v2 led to enhanced proliferation compared to pCL1 mock transduced cells. Furthermore, growth curves were determined by cell counting. Five days after transduction, the cells were re-plated at a density of 1000 cells/cm² in 12-well plates and were counted daily by using the Neubauer chamber for 5 days after plating. As shown in figure 4.11 B, cells overexpressing HAS3v2 grew significantly faster than pCL1 mock transduced cells, which led to an increasing difference in cell number.

Figure 4.11: **HAS3v2 overexpression leads to a pro-proliferative phenotype.**

(A): Cell proliferation was measured by CyQUANT NF proliferation assay kit, (n=4); (B): Growth kinetics were determined by cell counting, (n=4). * $p < 0.05$

4.5.2 ERK1/2 is phosphorylated in response to overexpression of HAS3v2.

As described in the previous section, HAS3v2 caused increased proliferation *in vitro*. One hypothesis was that HAS3v2 causes intracellular HA accumulation which in turn might induce intracellular signalling via RHAMM and activation of MAP-kinase pathway. Therefore, we investigated the phosphorylation level of ERK1/2, one of the MAP kinases, that directly interacts with RHAMM. Figure

Figure 4.12: **HAS3v2 enhances phosphorylation of ERK1/2.**

PT1590 human EAC cells were lentivirally transduced with either pCL1 mock or HAS3v2 over-expression, grown in 10 % FCS. The culture medium was changed to FCS-free medium 4 days after transduction to eliminate the exogenous stimuli. Proteins were harvested for immunoblot 24 hours after FCS-free treatment. **(A)**: Representative immunoblot of phosphorylated ERK and total ERK; intensity quantification of ERK **(B)** and phospho-ERK **(C)** immunoblots using fluorescent secondary antibodies and the Licor Odyssey imager. β -tubulin was taken as loading control (n=3). * $p < 0.05$

4.12 A shows that overexpression of HAS3v2 increased the phosphorylation of ERK1/2 dramatically. The increase in phosphorylation is more than 2 fold (shown in figure 4.12 C).

4.5.3 HAS3v2 enhances cell adhesion by inducing both expression and phosphorylation of focal adhesion kinase (FAK).

Furthermore, the cell adhesion was determined after overexpressing HAS3v2 in PT1590. Five days after transduction, cells were plated in the 96 well plates and were washed after 30 minutes. Cells attached to the plate were then stained with crystal violet. The absorption was measured by UV spectrometry at 540 nm. As shown in figure 4.13 A, overexpression of HAS3v2 causes increased cell adhesion ability. This might be due to the enhanced phosphorylation of focal adhesion kinase (FAK) as evidenced by western blotting (figure 4.13 B, D).

4.6 Functional analysis of HAS3v2 in xenograft model *in vivo*

4.6.1 Overexpression of HAS3v2 promotes tumor growth *in vivo*.

In order to study the physiological and pathological function, we overexpressed HAS3v2 in PT1590 cell with the lentiviral vector as described for the *in vitro* analysis. The mock vector, which led to the overexpression of EGFP, was used

Figure 4.13: **HAS3v2 enhances cell adhesion by inducing both expression and phosphorylation of focal adhesion kinase (FAK).**

PT1590 human EAC cells were lentivirally transduced with either pCL1 mock or HAS3v2 over-expression, grown in 10 % FCS. The culture medium was changed to FCS-free medium 4 days after transduction to eliminate the exogenous stimuli. Proteins were harvested for immunoblot 24 hours after FCS-free treatment. (A): Cell adhesion assay, (n=4); (B): Representative immunoblot of phosphorylated FAK and total FAK; intensity quantification of FAK (C) and phospho-FAK (D) immunoblots using fluorescent secondary antibodies and the Licor Odyssey imager. β -tubulin was taken as loading control (n=3). * $p < 0.05$

Figure 4.14: **Xenograft model of EAC**

PT1590 human EAC cells were lentivirally transduced with either pCL1 mock or HAS3v2 overexpression, grown in 10 % FCS. For xenografting, 1×10^6 cells were subcutaneously and bilaterally into the flanks of NMRI nu/nu mice at the age of 10 weeks. **(A)** Timecourse of tumor numbers; **(B)**: Cumulative tumor volume as determined by digital caliper; $n=9$ for pCL1 mock and $n=11$ for HAS3v2 overexpression.

as control. NMRI nu/nu mice were used for subcutaneous tumor formation. 1×10^6 PT1590 cells were injected into both flanks, and the mice were monitored for 35 days after xenografting. During the experimental period, tumor volumes were measured every 3 or 4 days. As illustrated in figure 4.14 B, the HAS3v2 overexpression group shows larger cumulative tumor volume compared to the mock group. Furthermore, tumors from the HAS3v2 overexpression group became visible earlier than the mock group. However, the number of tumors growing from both groups were similar 35 days after inoculation (figure 4.14 A).

After 35 days, the experiment was ended and tumor volume and tumor wet weight were determined. The results are shown in figure 4.15. The average tumor volume of group overexpressing HAS3v2 is significantly larger than of the mock group. Also, overexpressing HAS3v2 increases the tumor wet weight. Representative image from each group is shown in figure 4.15 C. These results suggest that the progression of HAS3v2 overexpressing tumors is faster than of the mock transduced tumors.

Figure 4.15: **HAS3v2 increases tumor volume and tumor wet weight in the xenograft model.**

PT1590 EAC cells were lentivirally transduced and xenografted into NMRI nu/nu mice. After 35 days, mock control (pCL1) and HAS3v2 overexpressing (oeHAS3v2) tumors were removed and tumor progression was compared. (A) Tumor volume was determined by digital caliper. (n=9-11); (B): Tumor wet weight (n=9-11); (C): Representative tumor image from each group. * $p < 0.05$

Figure 4.16: **Relative quantification of HAS3v2 mRNA from xenograft**

Total RNA was isolated from xenograft tumors derived from mock and HAS3v2 overexpression transduced PT1590 cells. After 35 days, NMRI nu/nu mice were sacrificed to remove tumors and gene expression was determined by RT-qPCR. (n=9-11). * $p < 0.05$

4.6.2 Overexpression of HAS3v2 in tumor cells leads to induction of HAS3 in stromal cells.

RNA from the xenograft tumor was isolated for realtime qPCR analysis. The tumor contains both human cancer cells and mouse stromal cells. Therefore, species specific primer pairs were designed to quantify the gene regulation of tumor and stroma separately. As shown in figure 4.16, HAS3v2 mRNA remains highly induced in tumor of the overexpression group at 35 days after innoculation. The expression level of HA related genes, namely HAS1, HAS2, HAS3v1, Hyal1, Hyal2, and HA receptors CD44s and RHAMM, were also quantified. For the quantification, species specific primers were used that allowed to distinguish between murine/stroma gene expression and human/tumor gene expression. In the tumors, the indicated genes were not significant regulated in response to HAS3v2 overexpression. However, murine HAS3v1 in the stroma of HAS3v2 overexpressing tumors was stimulated up to about 6 fold compared to the pCL1 mock group (figure 4.18, 4.17).

Figure 4.17: **Species specific expression profile of HA-associated genes in the xenograft, part A**

Total RNA was isolated from xenograft tumors derived from mock and HAS3v2 overexpression transduced PT1590 cells. After 35 days, NMRI nu/nu mice were sacrificed to remove tumors and gene expression was determined by RT-qPCR. Left column: human/tumor gene expression; right column: murine/stroma gene expression (n=9-11). * $p < 0.05$

Figure 4.18: **Species specific expression profile of HA-associated genes in the xenograft, part B**

Total RNA was isolated from xenograft tumors derived from mock and HAS3v2 overexpression transduced PT1590 cells. After 35 days, NMRI nu/nu mice were sacrificed to remove tumors and gene expression was determined by RT-qPCR. Left column: human/tumor gene expression; right column: murine/stroma gene expression (n=9-11). * $p < 0.05$

Figure 4.19: **Affinity histochemical analysis of HA in xenograft tumors**

PT1590 EAC cells were lentivirally transduced and xenografted into NMRI nu/nu mice. After 35 days, mock control (pCL1) and HAS3v2 overexpressing (oeHAS3v2) tumors were removed and analyzed with respect to HA accumulation by affinity histochemistry using biotinylated HABP. (n=9-11). Representative image from each group were selected. Magnification: 100 \times .

4.6.3 HA content in stroma is elevated in the HAS3v2 over-expression group.

Xenograft tumors were also analyzed by immunohistochemistry. Biotinylated HABP was used to detect hyaluronan in immunohistochemical analysis. As shown in figure 4.19, more HA was detected in the stroma of HAS3v2 over-expressing tumors compared to the mock control tumor. Tumorial associated hyaluronan showed no obvious difference between the HAS3v2 and the mock group. The accumulation of HA in stroma could be the consequence of HAS3v1 upregulation in murine stroma cells as shown in figure figure 4.18 and 4.17.

Figure 4.20: **Immunohistochemical analysis of proliferation in xenograft tumor**

PT1590 EAC cells were lentivirally transduced and xenografted into NMRI nu/nu mice. After 35 days, mock control (pCL1) and HAS3v2 overexpressing (oeHAS3v2) tumors were removed and analyzed with respect to proliferation rate by immunohistochemistry. Ki67 was stained as a proliferation marker. Cells, which are positive for the staining, indicate that they are in G1, S, G2 or M phase of the cell cycle. (n=9-11). Representative image from each group were selected. Magnification: 100 \times .

4.6.4 HAS3v2 induces proliferation *in vivo*.

In vivo proliferation rate was determined by immunohistochemical staining of the proliferation marker, Ki 67. Figure 4.20 shows that there were more Ki 67 cells after HAS3v2 overexpression compared to the mock group suggesting that HAS3v2 is also pro-proliferative *in vivo*.

4.7 Epidermal growth factor receptor (EGFR) signal cascades regulates the expression of HAS3v2.

4.7.1 EGF induces HAS3v2 mRNA expression in EAC cells.

EGF signaling plays an important role in the progression of different types of cancers including esophageal cancer. Therefore, we investigated whether the EGF signaling pathway may influence the expression of HAS3v2. PT1590 cells were starved in serum-free medium 24 hours before stimulation. Then, PT1590 cells were stimulated by epidermal growth factor with and without Cetuximab, a blocking antibody of the EGF receptor. Total RNA was harvested 4 hours and 24 hours after induction. As shown in figure 4.21, there was no significant regulation of HAS3v2 by EGF at 4 hours. However, 24 hours after EGF stimulation, strong upregulation of HAS3v2 was observed. This upregulation was completely blocked by Cetuximab. This result suggests that the EGFR signal cascade is able to regulate the HAS3v2.

4.7.2 The expression levels of EGFR and HAS3v2 are positively correlated in EAC.

EGFR is a member of ErbB family, which consists of four structurally related receptor tyrosine kinases. Overexpression or overactivity of EGFR has been shown to be associated with a number of cancers, including lung cancer and esophageal cancer. qPCR was performed to measure the EGFR mRNA expression level of the EAC samples introduced in section 4.4.2. For quantification, the data were normalized to the expression level of mucosa. Figure 4.22

Figure 4.21: **EGF stimulates HAS3v2 expression *in vitro*.**

PT1590 EAC cells were serum starved for 24 hours and stimulated with EGF (10 ng/ml) or EGF (10 ng/ml) plus Cetuximab (10 ng/ml) for 4 and 24 hours. HAS3v2 expression was determined by RT-qPCR. HAS3v2 mRNA expression was quantified for 4 hours after (A) stimulation and 24 hours after stimulation (A). Relative expression data was normalized to control. (n=6). $p < 0.05$

Figure 4.22: **mRNA expression level of EGFR in relationship to TNM staging in human EAC.**

mRNA expression was determined by RT-qPCR from tumor material removed during surgery. As control, healthy mucosal tissue from the circumstance of the excised tumors was used. Correlation coefficient method was used for statistic analysis. n=5 for T1, 16 for T2, 17 for T3 and 2 for T4, respectively.

Figure 4.23: **mRNA expression levels of EGFR and HAS3v2 are correlated in human EAC.** mRNA expression was determined by RT-qPCR from tumor material removed during surgery. As control, healthy mucosal tissue from the circumstance of the excised tumors was used. Correlation coefficient method was used for statistic analysis. $n=5$ for T1, 16 for T2, 17 for T3 and 2 for T4, respectively. The correlation between EGFR and HAS3v2 is analyzed in both mucosa group (A) and EAC group (B)

showed that the mRNA expression level of EGFR was related to the tumor staging. In addition, it was analyzed whether HAS3v2 and EGFR expression were correlated in both mucosa and EAC specimens. For the EAC group, a positive correlation between the expression level of HAS3v2 and EGFR was observed (figure 4.23 A). However, HAS3v2 shows no correlation with the EGFR in the mucosa group (figure 4.23 B). Taking together, the results suggested the EGF signaling pathway might be involved in the upregulation of HAS3v2 during EAC progression in patients.

Chapter 5

Discussion

5.1 HAS3v2 might be an intracellular HA synthase.

5.1.1 Intracellular HA originates from both endocytosis and *de novo* synthesis.

*H*yaluronan is a high molecular weight glycosaminoglycan generally regarded as an extracellular matrix molecule. The function of hyaluronan is to promote cell locomotion and proliferation, and it plays a role in wound healing and developmental processes such as cell differentiation and migration. In addition to its role in the extracellular matrix, hyaluronan has also been identified in the cytoplasm and nuclei of cells from different tissues both *in vivo* and *in vitro* [Margolis et al. 1976; Londoño and Bendayan 1988; Kan 1990; Ripellino et al. 1988; Egli and Graber 1995; Evanko and Wight 1999; Furukawa and Terayama 1977, 1979; Ripellino et al. 1989; Hascall et al. 2004; Evanko et al. 2004]. Furthermore, a number of hyaluronan binding proteins exist intracellularly that may be important in regulation of the cell cycle or in gene transcription [Hofmann et al. 1998; Grammatikakis et al. 1995; Deb and Datta 1996; Zhang et al. 1998]. For example, a vertebrate homologue of the cell cycle control protein CDC37 was cloned and found to bind hyaluronan [Grammatikakis et al. 1995], and an intracellular form of the hyaluronan receptor, RHAMM, was shown to regulate ERK kinase activity [Zhang et al. 1998].

The source of intracellular hyaluronan is not yet clear. Evanko and Wight showed that hyaluronan could be taken up by endocytosis from the extracellular space [Evanko and Wight 1999]. However, exogenous fluoresceinated hyaluronan was confined to the endosomes and did not co-localize with the endogenous hyaluronan network in the cytoplasm, suggesting that some of the

Figure 5.1: **Scheme of possible sources of intracellular hyaluronan**

Intracellular HA originated from endocytosis (1) and possibly also from intracellular *de novo* synthesis (2). However, the site organelle where intracellular *de novo* synthesis of HA occurs is not known. N, nucleus; PM, plasma membrane.

cytoplasmic hyaluronan must be derived from intracellular sources and not from internalization of extracellular hyaluronan (figure 5.1). No evidence indicates that HAS1, HAS2, and HAS3v1 can synthesize hyaluronan inside the cell, which might be due to their plasma membrane localization. This rises the suggestion that there is another active hyaluronan synthase localized inside the cell [Evanko and Wight 1999].

5.1.2 Evidence for the activity of HAS3v2

There are three hyaluronan synthase isoforms in human, namely HAS1, HAS2, and HAS3 [Spicer et al. 1997b]. It is shown that all three HAS isoforms are localized on the plasma membrane and synthesize extracellular hyaluronan [Weigel et al. 1997]. Human hyaluronan synthases are transmembrane proteins that contain seven putative transmembrane domains [Weigel et al. 1997]. The intracellular loop between the 2nd and the 3rd transmembrane domain is predicted to be the catalytic center [Yoshida et al. 2000]. A cysteine residue in the intracellular loop is reported to be highly conserved from bacterial to mammalian HAS and the modification of this cysteine can partially inhibit enzyme activity [Weigel et al. 1997]. This suggests that the cysteine residue is critical for HAS enzymatic activity.

Human HAS3 has two splicing variants, namely HAS3v1 and HAS3v2 [Sayo et al. 2002; Monslow et al. 2003]. HAS3v2 is the shorter splicing variant of HAS3 and consists of only 281 amino acids (553 AA for HAS3v1). HAS3v2 shows only 2 transmembrane domains in *in silico* analysis. Instead of intracellular loop, HAS3v2 contains an intracellular c-terminal end of 215 AA in length, which also contains the highly conserved cysteine residue (shown as black circle in figure 1.2). This raises the possibility that HAS3v2 might also be an active hyaluronan synthase despite of its truncated size. In order to identify the activity center in HAS3v2, protein functional analysis was performed *in silico* using Pfam database [Finn et al. 2008]. The only functional domain, glycosyl transferase 2 domain, is shared by both HAS3 splicing variants. This protein domain is presented in all the active hyaluronan synthases found so far [Weigel and DeAngelis 2007]. The glycosyl transferase 2 domain reaches from AA 88 to AA124 in both HAS3v1 and HAS3v2. This indicates the potential role of

HAS3v2 in HA synthesis. In addition, we performed a 3D protein structure simulation for the intracellular loop of HAS3v1 and the intracellular c-terminal end of HAS3v2, where the glycosyl transferase 2 domain is localized. The similarity of 3D protein structure of HAS3 splicing variants was analyzed based on an overlay algorithm [Soding 2005; Soding et al. 2005]. As shown in figure 4.2, the green part indicates highly similar regions in protein conformation between HAS3v1 and HAS3v2. Of note, the glycosyl transferase 2 domain is also localized in this overlay.

Furthermore, *in silico* analysis revealed that HAS3v2 contains an evolutionary conserved cysteine which is proofed to be critical for the HAS enzymatic activity. HAS3v2 also shares the glycosyl transferase 2 domain with other active hyaluronan synthases. Furthermore, predicted 3D protein structures of the putative active center from HAS3v1 and HAS3v2 are similar. All these results suggest that HAS3v2 could be an active hyaluronan synthase. Therefore, functional studies of HAS3v2 were performed.

HAS3v2 is predicted to have only 2 transmembrane domains. However, there are 7 transmembrane domains presented on the other HAS isoforms, i.e. HAS1, HAS2 and HAS3v1 [Weigel et al. 1997]. Thus, it was not clear whether HAS3v2 does also localize to the plasma membrane.

As reported, the N-terminal GFP-HAS2 and GFP-HAS3v1 fusion proteins are active with respect to HA synthesis [Rilla et al. 2005; Kultti et al. 2006]. The first 261 AA sequence on the N-terminal of HAS3v2 protein is identical to HAS3v1. Therefore, N-terminal YFP-HAS fusion proteins were constructed to investigate the subcellular localization of HAS3v2 (shown in figure 4.3). The results indicated that HAS3v2 was not localized in the plasma membrane but on the ER inside the cell. By protein translation, the predicted intracellular parts of

Figure 5.2: **Intracellular HA originates from both endocytosis and *de novo* synthesis.**

Fluoresceinated hyaluronan (Green) is uptaken by endocytosis (**A**), and the cells were further stained for intracellular HA (Red) (**B**). Bars = 25 μm . Images were taken from [Evanko and Wight 1999]

the protein reside in the outer membrane part of ER. Therefore, the c-terminal tail of HAS3v2 might extend of the outer ER membrane. If HAS3v2 was active, it could synthesize HA on the ER membrane. This might provide an explanation why intracellular HA was accumulated on the outer ER membrane but not in the ER lumen [Evanko and Wight 1999]. Further, Evanko and Wight showed that endocytosis of the exogenous hyaluronan is not the only source of intracellular HA (figure 5.2). Hyaluronan remains attached to HA synthases during synthesis [Kyosseff and Weigel 2007]. Thereby, HA would remain localized on the outer ER membrane during its synthesis by HAS3v2 and this could, at least partially, compliment the intracellular HA localization pattern besides endocytosis of exogenous hyaluronan.

HAS3v2 was overexpressed in both HEK cells and skin fibroblasts. Then, intracellular HA was quantified using HA ELISA. HAS3v2 caused increased intracellular HA level in both cell lines. In addition, intracellular HA images were taken by confocal microscope. The vesicular staining pattern in the cytosol might due to the endocytosis of exogenous HA [Evanko and Wight 1999]. In addition, a network-like intracellular HA signal (shown in figure 4.7, white arrow

indicated compared to white star in mock group) was detected. This pattern could not be explained by the endocytosis but might be due to the intracellular *de novo* synthesis on the surface of ER by HAS3v2.

Hyaluronan is attached to the HAS during the synthesis [Kyosseff and Weigel 2007]. Enzymatic capture assay experiments showed that a HA-HAS3v2 complex exists in microsome preparations after supplementation with activated UDP-sugars. However, the experiment was performed using microsomes isolated from transfected HEK cells. Microsomes consisted of raw membranes, mainly derived from ER and golgi apparatus. However, minor proportions of plasma membrane could have been included. Therefore, hyaluronan could have also been synthesized by HAS1, HAS2 and HAS3v1 originating from the plasma membrane. One possible alternative explanation for the fact that HA-HAS3v2 complexes were detected is that the HAS3v2 binds to hyaluronan that was synthesized by HAS1-3 from plasma membrane contamination. However, that would require that HAS3v2 is at least a HA binding protein.

Currently, there are two known HA binding domain, namely LINK and GLA domain [Day and Prestwich 2002]. Pfam and SMART (<http://smart.embl-heidelberg.de/>) databases contain large collections of protein families [Finn et al. 2008; Schultz et al. 1998; Ponting et al. 1999; Letunic et al. 2009]. Neither LINK nor GLA domains were detected on HAS3v2 by analyzing through both pfam and SMART databases. Further, overexpression of HAS3v2 led to increased intracellular HA levels. Furthermore, if HAS3v2 was a HA binding protein, the only possible explanation for increased intracellular HA is that HAS3v2 binds to hyaluronan and protect it from hyaluronidase digestion. However, hyaluronidase digestions completely eliminated hyaluronan on both permeabilized HAS3v2 overexpressing skin fibroblasts and microsomes isolated from HAS3v2 transfected HEK cell.

Thus, no protecting effect could be observed. Therefore, the enzymatic capture assay strongly suggested the activity of HAS3v2 as hyaluronan synthase.

5.2 HAS3v2 is a potential tumor marker for EAC.

Esophageal cancer is the 6th most frequent cancer worldwide [Parkin et al. 1999]. Squamous cell carcinoma (ESCC) and adenocarcinoma (EAC) are the two main subtypes of esophageal cancer [Blot 1995]. The prognosis for both subtypes is rather poor with a 5-year relative survival rate between 11% and 15% [Lagarde et al. 2006]. Hyaluronan is known to be important for tumor progression in various cancer types [Auvinen et al. 2000; Ropponen et al. 1998; Lipponen et al. 2001; Anttila et al. 2000; Setälä et al. 1999]. HA synthesis is correlated with the mRNA level of HAS isoforms. Therefore, we first analyzed the regulation of HAS isoforms during tumor progression of both ESCC and EAC.

HAS3v2 was highly upregulated in EAC, but not in ESCC, compared to the mucosa group. However, the expression levels of other HAS isoforms remained constant in EAC. Importantly, the HAS3v2 expression level was also correlated to the tumor staging. This indicates that HAS3v2 is a potential tumor marker for esophageal adenocarcinoma. In addition, HAS3v2 induced intracellular hyaluronan accumulation, that often correlates with cell proliferation [Evanko and Wight 1999]. Elevated cytosolic HA was detected in different cancer types [Corte et al. 2006; Vizoso et al. 2004; Ruibal et al. 2003]. Further, intracellular HA binding protein RHAMM was reported to play important roles in tumor progression [Giannopoulos and Schmitt 2006; Hus et al. 2008; Rein et al. 2003; Tölg et al. 2003; Yamano et al. 2008; Zlobec et al. 2008]. These

facts encouraged us to study the pathological function of HAS3v2 in esophageal adenocarcinoma.

5.3 HAS3v2 is a candidate for an oncogene.

5.3.1 RHAMM pathway promotes tumor progression.

Both CD44 and RHAMM are hyaluronan receptors and play important roles in regulating cell behaviors including tumor progression [Turley et al. 2002]. CD44 is a transmembrane protein, while RHAMM is located on the plasma membrane as well as in the cytosolic compartment [Turley 1980]. The basal expression level of RHAMM is low in normal tissue [Turley et al. 2002; Evanko et al. 2007; Slevin et al. 2007]. However, it is reported to be highly expressed in several advanced cancers [Giannopoulos and Schmitt 2006; Hus et al. 2008; Rein et al. 2003; Tolg et al. 2003; Yamano et al. 2008; Zlobec et al. 2008; Pujana et al. 2007]. According to the observations, one might speculate that excessive cytosolic RHAMM might be activated by intracellular HA and in turn induce tumor progression. Therefore, HAS3v2 regulated cell phenotype might be mediated through the RHAMM signaling pathway.

5.3.2 HAS3v2 might induce the RHAMM signaling pathway to regulate cell behavior.

Overexpression of HAS3v2 increases the proliferation rate both *in vitro* and in xenograft experiments in nude mice. One reason is that the ERK1/2 kinase phosphorylation was induced by overexpression of HAS3v2. ERK1/2 phospho-

Figure 5.3: **HAS3v2 might regulate cancer cell phenotype through RHAMM.**

HAS3v2 overexpression leads to intracellular HA accumulation. The intracellular HA might bind to RHAMM to induce phosphorylation of the ERK kinase. Phosphorylated ERK can induce cell proliferation by activating the ERK signaling cascades. After binding to intracellular HA, RHAMM can also translocate to the plasma membrane and interact with PDGF receptor in an autocrine manner. Consequently, activated PDGF receptor can phosphorylate focal adhesion kinase (FAK). This leads to improved cell adhesion. Phosphorylated FAK can also contribute to the ERK phosphorylation to promote cell proliferation.

rylation can be enhanced through the RHAMM signal cascade and thereby induce the cell proliferation [Turley et al. 2002]. This leads to the hypothesis that HAS3v2 can increase the intracellular HA and that intracellular HA can trigger the RHAMM signaling pathway (shown in figure 5.3). After activation, ERK1/2 kinase activates further signal cascades either by phosphorylation of downstream targets like ELK1 or by translocating to the nucleus to initiate downstream protein expression and thereby promote cell cycle progression.

Protein export is considered to be dependent upon access to the classical secretory pathway through the ER/Golgi route [Hathout 2007; Simpson et al. 2007]. Protein secretion through this route requires an N-terminal signal peptide, that is responsible for most of the constitutive export of proteins [Hathout 2007; Simpson et al. 2007]. However, the primary structure of RHAMM lacks this signal peptide for classical secretion [Maxwell et al. 2008]. Emerging evidence reveals that some cytoplasmic proteins, e.g. RHAMM, can be exported via an alternative mechanism that does not require the known structural secretion cues (shown in figure 5.4) [Chivasa et al. 2006, 2005; Tjalsma et al. 2006]. Therefore, RHAMM may be activated by interacting with intracellular hyaluronan and the activated HA-RHAMM complex is subsequently exported to the ECM through the non-conventional protein export routes. Specifically, one RHAMM splicing variant (splice variant xy) has been shown to interact with the PDGF receptor and to trigger the PDGF pathway. However it has not been demonstrated directly whether HA binding to RHAMM is necessary for this transactivation of the PDGF receptor [Zhang et al. 1998]. Activated PDGF signaling pathway can stimulate FAK phosphorylation [Turley et al. 2002]. Therefore, intracellular activation of RHAMM, translocation of RHAMM to the extracellular compartment and activation of a growth factor receptor that crosstalks to focal adhesion complexes and FAK may be responsible for the result presented here that HAS3v2

Figure 5.4: **Routes for non-conventional protein export**

(A) **Transporter channels.** Cytoplasmic proteins can be exported through transporter-protein channels and then captured by cell-surface counter receptors. As an example, FGF2 is shown being exported through the ABC transporter and then captured by a heparin sulphate proteoglycan [Nickel 2005; Prudovsky et al. 2008 Apr 1]. (B) **Protein-release complex.** Other cytoplasmic proteins, such as epimorphin, associate with a protein-release complex that is composed of S100A13 and synaptotagmin 1 that then binds to annexin 2. The epimorphin protein-release complex is localized to, and flipped through, the cytoplasmic membrane in response to Ca^{2+} and phosphatidylserine. Released epimorphin then binds to α_v -integrin, resulting in activation of morphogenic signaling cascades [Radisky et al. 2003]. (C) **Flippase activity.** An alternate route of export results from cytoplasmic proteins binding to transporter proteins that have intrinsic flippase activity when stimulated by phosphatidylserine [Daleke 2003]. (D,E) **Exocytosis and membrane blebbing.** Additional mechanisms of non-conventional export include exocytosis (D) and membrane blebbing (E). Cytoplasmic and/or nuclear proteins such as Ku are released by exocytosis of exosomes [Paupert et al. 2007], but cytoplasmic proteins can also be exported in vesicles formed by membrane blebbing [Huot et al. 1998]. Figure was taken from [Maxwell et al. 2008]

overexpression causes elevated FAK phosphorylation and cell adhesion in vitro. Phosphorylated FAK can further stimulate ERK phosphorylation and thereby lead to an amplified ERK signaling response and proliferation. Taken together, as a working hypothesis it is proposed that RHAMM is activated by intracellular HA and then exported to the ECM to trigger the PDGF pathway through direct interaction with PDGF receptor. Figure 5.3 shows the hypothetical scheme of HAS3v2 mediated RHAMM signaling pathway. In future experiments, it should be addressed if the effects of HAS3v2 overexpression are indeed dependent on RHAMM and/or a growth factor receptor.

5.3.3 Stroma cells can also be influenced by HAS3v2 upregulation in cancer cells.

Immunohistochemical analysis revealed increased hyaluronan in the stroma but not around cancer cells after xenografting HAS3v2 overexpressing EAC cells. The expression level of HAS3v1 in stroma was upregulated by HAS3v2 overexpression in cancer cells as determined by mouse specific analysis of HAS3v1 mRNA expression. The upregulation of stromal HAS3v1 explained the increase of stromal hyaluronan. One possible explanation for the induction of stromal hyaluronan in this model is that the overexpression of HAS3v2 activated via RHAMM the malignant phenotype of the xenografted EAC cells (shown in figure 5.5). These activated EAC in turn released factors such as growth factors or cytokines that stimulated the stromal cells to express HAS3v1. In efficient pathway how HAS3v1 is induced is the activation of NF- κ B, which was confirmed by promoter analysis [Monslow et al. 2003].

Quantitative PCR results indicated that the mRNA levels of HAS1, HAS2 and

HAS3v1 in cancer cells are high enough to perform HA synthesis. However, by affinity histochemistry the cancer cells were nearly all HA negative except the outer layer of the cancer colonies that were in contact with stromal cells. The HA poor phenotype could be explained by the hypothesis that the cancer cells inside the tumor are lacking of the substrates for HA synthesis, namely UDP-glucuronic acid and UDP-glucosamine. This may also explain why there was no intracellular HA accumulation despite of strong overexpression of HAS3v2. Alternatively, the tumor cells degrade hyaluronan and generate small hyaluronan fragments that can not be stained by HABP.

Taking together, HAS3v2 induced tumor proliferation and cause changes in the stroma environment that might also contribute to tumor progression.

5.3.4 Other intracellular hyaladherins might be involved in HAS3v2 mediated signal transduction.

IHABP4 is a HA binding protein localized in the cytosol and nucleus [Huang et al. 2000]. Upregulation of IHABP4 is observed in several cancer types [Kobarg et al. 1997]. IHABP4 interacts with RACK1 and regulates the cell survival by inducing the protein kinase C pathway [Nery et al. 2004]. In addition, human CDC37 was also identified to be an intracellular HA binding protein, whose homologue in *Saccharomyces cerevisiae* functions as a cell division cycle control protein [Grammatikakis et al. 1995]. Furthermore, HABP1 is detected as an intracellular hyaladherin as well, although it is found also on the plasma membrane and thereby promote cell adhesion [Gupta et al. 1991; Gupta and Datta 1991; Muta et al. 1997; Dedio et al. 1998; Simos and Georgatos 1994]. HABP1 is highly expressed in various cancer types including esophageal adenocarci-

Figure 5.5: **HAS3v2 regulates both cancer and stromal cell phenotype through RHAMM**

Overexpression of HAS3v2 in cancer cells induces cell proliferation and adhesion possibly through RHAMM signaling cascade. RHAMM can be activated by binding to intracellular HA and translocated to the plasma membrane. There, activated RHAMM might also interact with the PDGF receptor of stromal cells in a paracrine manner. This can induce the FAK phosphorylation in stromal cells. The transcriptional factor, NF- κ B is a downstream target of the FAK signaling pathway. Promoter analysis revealed NF- κ B binding sites in the putative promoter region of HAS3v1. After activation, NF- κ B can translocate into the cell nucleus and promote HAS3v1 expression. Consequently, the upregulation of HAS3v1 in stromal cells leads to increased HA in stromal part of the tumor.

noma [Rubinstein et al. 2004]. Taking together, intracellular HA accumulation by HAS3v2 overexpression may lead to interaction between hyaluronan and those intracellular hyaladherins. Further experiments will be needed to prove whether intracellular hyaladherins are involved in the observed biological effects of HAS3v2.

5.3.5 Natural antisense RNA effect of HAS3v2

DERPC (Decreased Expression in Renal and Prostate Cancer) is a novel tumor repressor gene. Human DERPC is localized on the chromosome 16q22.1 close to human HAS3. The expression level of DERPC is observed to be downregulated in prostate and renal cancer [Sun et al. 2002], but shows no regulation during breast cancer progression [Green et al. 2009]. Overexpression of DERPC leads to inhibited proliferation of prostate cancer cells *in vitro* [Sun et al. 2002]. As shown in figure 5.6, mRNA of DERPC is complementary to the mRNA of HAS3v2. Complementary RNA can cause RNA degradation due to the mechanism of RNA interference (RNAi) [Werner et al. 2009]. This means upregulation of HAS3v2 mRNA can lead to the downregulation of DERPC. Consequently, cell proliferation rate might be enhanced due to the downregulation of the proliferation repressor, DERPC.

5.4 Therapeutic implications for HAS3v2 in cancer

There are various alterations that affect EGF receptor (EGFR) in human cancers [Henson and Gibson 2006]. EGFR is often mutated in the intracellular domain rendering the tyrosine kinase constitutively active. Furthermore, some tumors

Figure 5.6: **HAS3v2 mRNA contains an antisense sequence against DERP**

The mRNA complementary region between HAS3v2 and DERP is indicated as ||. DERP consists of three splicing variants and all of them contain the complementary sequence against HAS3v2.

increase the production of EGF-related growth factors leading to the persistent activation of ErbB receptors, which play important roles in tumor progression [Zhang et al. 2007].

Activation of the EGF receptor results in autophosphorylation of key tyrosine residues (figure 5.7) [Yarden 2001; Jorissen et al. 2003]. These tyrosine phosphorylation sites allow proteins to bind through their Src homology 2 (SH2) domains and lead to the activation of downstream signalling cascades including the RAS/extracellular signal regulated kinase (ERK) pathway, the phosphatidylinositol 3-kinase (PI3) pathway and the Janus kinase/Signal transducer and activator of transcription (JAK/STAT) pathway [Kisseleva et al. 2002]. These pathways act in a coordinated manner to regulate cell behavior, e.g. cell survival.

EGF signaling pathway has become a therapeutic target for cancer treatment [Zhang et al. 2007]. Cetuximab is a monoclonal antibody that prevents EGFR signaling by binding to the ligand binding and receptor dimerisation domains and is approved for treatment of colorectal and head-neck cancer [Van Cutsem et al. 2009; Egloff and Grandis 2009]. Further understanding of EGF signaling will undoubtedly improve the understanding of oncogenesis and possibly provide

Figure 5.7: **Scheme of EGFR signaling pathway**

Activation of the EGF receptor results in autophosphorylation of key tyrosine residues within the EGFR. These tyrosine phosphorylation allow adaptor proteins to bind through their Src homology 2 (SH2) domains and leads to the activation of downstream signalling cascades including the RAS/extracellular signal regulated kinase (ERK) pathway, the phosphatidylinositol 3-kinase (PI3) pathway and the Janus kinase/Signal transducer and activator of transcription (JAK/STAT) pathway. These pathways act in a coordinated manner to promote cell survival.

novel targets for therapeutic intervention.

EGF was identified here to stimulate the expression of HAS3v2 *in vitro*. Importantly, the expression of HAS3v2 and EGFR in EAC patients are correlated. This suggested that HAS3v2 could be regulated by EGFR signaling both *in vitro* and *in vivo*. If HAS3v2 was a functional downstream target of EGFR in tumor, it could contribute to increased cancer cell proliferation and adhesion in response to EGF. Therefore, reduction of HAS3v2 expression might be one aspect of the anti-cancer effect of EGF-inhibitory pharmacology. However, it might also be considered that HAS3v2 could play a role for the occurrence of tumors resistant to anti-EGF therapy and HAS3v2 could be targeted specifically.

5.5 Open questions and perspective

The data presented in this thesis give rise to many further questions that will be addressed in future experiments.

1. HAS3v2 is shown to be located on the ER. However, no known ER retention signal was found on the AA sequence of HAS3v2 by *in silico* analysis. Therefore, the mechanism of ER targeting of HAS3v2 needs to be identified.
2. Recombinant HAS3v2 could be purified from hyaluronan deficient organisms, such as *E. coli*. HAS enzymatic capture assay with purified HAS3v2 protein could further proof that HAS3v2 is indeed an active hyaluronan synthase.
3. Promoter analysis of HAS3v2 could discover regulatory mechanisms in addition to EGFR signaling pathway.

4. Specific antibody is required to detect HAS3v2 in protein expression.
5. It is impossible to knock down the HAS3v2 specifically by RNAi due to the transcriptome structure. A neutralization antibody to HAS3v2 might be a promising option to advance the experimental data on HAS3v2 function and to test the potential therapeutic value.

Chapter 6

Summary

*H*yaluronan is a large glycosaminoglycan mainly presented in the extracellular matrix as well as in the intracellular compartment. Hyaluronan is synthesized by three hyaluronan synthase isoforms, namely HAS1, HAS2 and HAS3. HAS3v2 is a smaller splicing variant of HAS3 with 281 AA in length. Here, biological and pathological functions of HAS3v2 were investigated for the first time.

HAS3v2 localizes on membrane of the endoplasmic reticulum as shown by stable overexpression of YFP-HAS3v2 fusion protein. Overexpression of HAS3v2 leads to increased intracellular hyaluronan. A HA-HAS3v2 complex was also detected in microsomes of YFP-HAS3v2 overexpressing cells using the HAS enzymatic capture assay. This indicated HAS3v2 is an intracellular hyaluronan synthase or at least HA binding protein.

Esophageal cancer is one of the 10 most frequent tumor types worldwide, which is distinguished into two major subtypes: squamous cell carcinoma (ESCC) and adenocarcinoma (EAC). HAS3v2 is upregulated only in human EAC and also correlated with TNM staging. This suggested that HAS3v2 is a potential tumor marker for EAC. Lentiviral overexpression of HAS3v2 promotes cell proliferation rate both *in vitro* and after xenografting of HAS3v2 overexpressing EAC cells in nude mice. This phenotype was, at least partially, caused by enhanced ERK1/2 kinase phosphorylation. HAS3v2 also stimulated the phosphorylation of focal adhesion kinase (FAK) and improve EAC cell adhesion. Both phosphorylations could be the consequence of activated RHAMM signaling. Overexpression of HAS3v2 in cancer cells also stimulated HAS3v1 mRNA expression in stromal cells of EAC xenograft, which led to increased stromal HA levels. The stromal HA has been reported to provide microenvironment in favor for progression and metastasis.

The expression of HAS3v2 in EAC was regulated by EGF pathway and the blocking antibody of EGFR, Cetuximab, diminished the EGF-induced HAS3v2 upregulation. Furthermore, the mRNA expression of HAS3v2 and EGFR are positively correlated in EAC patients.

Taken together, HAS3v2 promotes malignant tumor cell phenotype and could be a diagnostic oncogene and a potential therapeutic target for EAC.

Appendix B

Acknowledgement

Acknowledgement

First of all, I want to thank Prof. Jens W. Fischer for giving me the opportunity to work on this highly interesting research topic in his lab and also providing me extraordinary supports throughout the whole project. His organization and encouragement for our group is truly the basis of this work.

I would like to extend my gratitude to our colarborition partners: Dr. Christian Mielke and Prof. Boege for the pMC vector and instructions for stably expression cell line construction; Dr. Stöcklein for patients' biopsies and PT1590 cells; Prof. Hanenberg for lentiviral expression system; Prof. Reifenberger for skin fibroblasts; Prof. Ehrmann, Dr. Sonja Hasenbein and Dr. Michael Meltzer for the help of *in silico* analysis.

Furthermore, I would like to thank all my great colleagues from our group. It was so lucky for me to work with you guys.

Especially, I would like to thank Kirsten for all the experimental supports. It is such a nice experience to work with you!

For Annika and Annette, thanks a lot for the help in immunohistochemistry.

I thank Ariane for her instruction on many techniques and the kind help regarding to the HAS enzymatic capture assay.

To Till, a continual source of support and friendship, I owe a great deal.

Also, I would like to thank Ms. Sieberg and Ms. Görtz for the institute organization.

I express my enduring love and thanks to my parents who have always been there to encourage and support me.

Finally, I would like to thank my wife, Guwa Gegen, for her continual encouragement and support. You have been there through it all.

Appendix C

Abbreviations

bHAbp	BIOTINYLATED HA BINDING PROTEIN
Da	DALTON
ECM	EXTRACELLULAR MATRIX
ERK	EXTRACELLULAR-SIGNAL REGULATED KINASE
EGF	EPIDERMAL GROWTH FACTOR
EGFR	EPIDERMAL GROWTH FACTOR RECEPTOR
FACS	FLUORESCENCE ACTIVATED CELL SORTER
FAK	FOCAL ADHESION KINASE
FGF	FIBROBLAST GROWTH FACTOR
GAG	GLYCOSAMINOGLYCAN
GlcA	GLUCURONIC ACID
GlcNAc	N-ACETYLGLUCOSAMINE
HA	HYALURONAN
HAbp	HA BINDING PROTEIN
HAS	HYALURONAN SYNTHASE
HYAL	HYALURONIDASE
I α I	INTER-ALPHA-INHIBITOR
IHABP	INTRACELLULAR HA BINDING PROTEIN
IL-1 β	INTERLEUKIN-1 BETA
KB	KILLOBASE
MAP	MITOGEN ACTIVATED PROTEIN
MAPK	MITOGEN ACTIVATED PROTEIN KINASE
MEK	MITOGEN ACTIVATED EXTRACELLULAR RESPONSE KINASE
MEKK-1	MAPK/ERK KINASE KINASE
MMP	MATRIX METALLOPROTEINASE
NF κ B	NUCLEAR FACTOR KAPPA-B
PDGF	PLATELET DERIVED GROWTH FACTOR
PI3K	PHOSPHOINOSITIDE 3-KINASE
PKC	PROTEIN KINASE C
RHAMM	RECEPTOR FOR HYALURONIC ACID MEDIATED MOTILITY
TLR	TOLL-LIKE RECEPTOR

Appendix D

Curriculum Vitae

Personal Information

Name:	Guang Dai
Date of Birth:	July 25 th , 1978
Place of Birth:	Shenyang, Liaoning Province
Nationality:	China
Family status:	married (Guwa Gegen) since August 2005
Address:	Overbeckstr. 16, 45147, Essen

Education

2006.01 - now	Dusseldorf University / Duisburg Essen University <i>Ph.D Thesis</i>
2002.10 - 2004.10	Dresden University of Technology <i>Master's Degree in Molecular Bioengineering</i>
1996 - 2000	Liaoning University in China <i>Bachelor's Degree in Biotechnology</i>

Essen, October 10, 2009

(Guang Dai)

Appendix E

Erklärung

Erklärung:

Hiermit erkläre ich, gem. §6 Abs. 2, Nr. 8 der Promotionsordnung der Math.-Nat.- Fachbereiche zur Erlangung der Dr. rer. nat., dass ich das Arbeitsgebiet, dem das Thema "Functional analysis of human hyaluronan synthase 3 splicing variant 2" zuzuordnen ist, in Forschung und Lehre vertrete und den Antrag von Herrn Guang Dai befürworte.

Essen, den 12.10.2009

(Prof. Jens W. Fischer)

Erklärung:

Hiermit erkläre ich, gem. §6 Abs. 2, Nr. 6 der Promotionsordnung der Math.-Nat.- Fachbereiche zur Erlangung des Dr. rer. nat., dass ich die vorliegende Dissertation selbständig verfasst und mich keiner anderen als der angegebenen Hilfsmittel bedient habe.

Essen, den 12.10.2009

(Guang Dai)

Erklärung:

Hiermit erkläre ich, gem. §6 Abs. 2, Nr. 7 der Promotionsordnung der Math.-Nat.- Fachbereiche zur Erlangung des Dr. rer. nat., dass ich keine anderen Promotionen bzw. Promotionsversuche in der Vergangenheit durchgeführt habe und dass diese Arbeit von keiner anderen Fakultät abgelehnt worden ist.

Essen, den 12.10.2009

(Guang Dai)
